Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

*To my love, my wife Ana Maria
and our children Sarah, Eli, and Jake
for their unwavering love and support.*

In Memoriam

To my father, Louis Wenig (1926-2014), devoted son, husband, father, grandfather, and great-grandfather, athlete, World War II veteran, good guy, and pillar of his community who so ably provided for his family and set a standard for all of us to follow. I love you Dad and miss you.

To my mother-in-law, Ursula Karin Klostermann Urrutia (1928-2014), loving mother, grandmother, and great-grandmother whose strong will and opinions are sorely missed by everyone who knew her.

To my uncle-in-law, Juan José Urrutia, MD (1932-2014), the standard-bearer of his family who lived an exemplary life; his quiet and confident demeanor served as example for all of his family.

Preface to the Third Edition

It has been a daunting task to undertake revising this atlas not so much for the dedicated time and effort committed to completing it but for keeping apprised of all the new information that appears in the literature on a near daily basis. Molecular diagnostics has reached the “prime time” in assisting physicians in managing their patients, specifically (but not solely) in the advances achieved in targeted therapy offering better outcomes and, more importantly, hope to patients and their families in treating diseases that previously were considered to be untreatable/incurable. For pathologists, advances in molecular biology have provided a better understanding of the diseases we diagnose. However, relative to compiling a book such as this one, the advances in molecular biology are akin to a moving target with near weekly publications that provide new information and/or information that renders previous knowledge relative to a given disease essentially moot. I have to the best of my ability tried to provide the most current information relative to the diseases included in this atlas. I sincerely hope I have succeeded in this endeavor or to at least have made this atlas a valuable resource to a wide spectrum of individuals with interest in diseases of the head and neck.

The third edition of the *Atlas of Head and Neck Pathology* updates and revises the information detailed in the second edition. I have attempted to correct any/all mistakes that were present in the previous edition. As in the second edition, this third edition is an attempt to be as complete as possible relative to diseases of the head and neck within the context of the atlas format. The format of the atlas remains similar to that of the previous editions, with information provided in accessible bulleted statements rather than in a narrative style. The changes in this edition include separate sections on the pharynx and the neck previously subsumed within the section on the oral cavity in the second edition. Various sections have been expanded to include more disease-specific entities including but not limited to odontogenic lesions/neoplasms in the Oral Cavity Section. Molecular diagnostics has become integral to diagnostic surgical pathology, and I have tried to include as much relevant molecular diagnostic information as it applies to the identification of new diseases/neoplasms, the understanding of disease/neoplastic pathogenesis, and the advances in treatment and prognosis. The illustrations are a key component of any atlas. To this end,

there are 3338 images in the third edition, including approximately 1570 new images.

Over the past nearly 30 years, I have been fortunate to have worked in three superb medical facilities. I began my pathology career in the Department of Otorhinolaryngic and Endocrine Pathology at the Armed Forces Institute of Pathology (AFIP) in Washington, DC, in 1986, mentored by Drs. Vincent Hyams and Dennis Heffner in the Division of Otorhinolaryngic Pathology, and Clara Heffess, MD, in the Division of Endocrine Pathology. Subsequent to my joining the staff at AFIP, our department added Drs. Carol Adair and Lester Thompson, creating one of the strongest diagnostic divisions in all of the AFIP. Close collaboration with the Oral and Maxillofacial Pathology Division at AFIP allowed me to learn and collaborate with their many outstanding oral pathologists. I am forever grateful for having been given the opportunity to work at the AFIP and honored to have served on active duty in the United States Navy.

In 1998 I joined the Department of Pathology at the Albert Einstein College of Medicine, Bronx, New York. Under the leadership of Michael Prystowsky, MD, PhD, I was fortunate to work in an environment that fostered and valued diagnostics, research, and education. In 2001, I moved to the Department of Diagnostic Pathology and Laboratory Medicine at Continuum Health Partners in New York City that included Beth Israel Medical Center, St. Luke's Hospital, and Roosevelt Hospital thanks to the support of the Chairman, Neville Colman, MD, PhD, whose unfortunate death in 2003 was a blow to the entire Health System. Over the past 14 years spent at Continuum Health Partners, I have worked with an outstanding group of diagnostic surgical pathologists and have appreciated their support of me, of the Department, and of the Health System. These past 14 years also brought together a unique core of high-level and accomplished physicians focused on providing care to patients with diseases of the head and neck. This multidisciplinary team of clinicians has included Drs. Louis Harrison, Roy Sessions, Mark Persky, Mark Urken, Ken Hu, Roy Holiday, Bruce Culliney, and Jean-Marc Cohen, creating one of the strongest groups of physicians focused on diseases of head and neck within New York and the United States. Change is inevitable, and in 2013, Continuum Health Partners merged with the Mount Sinai Hospital to

create the Mount Sinai Health System. The Department of Pathology under the leadership of Carlos Cordon-Cardo, MD, PhD, is among the largest in the United States. Once again I am fortunate to be in a department led by an individual who provides an environment that fosters academics, diagnostics, and education.

I would like to acknowledge my brother Barry L. Wenig, MD, my sister Hally Frist, and my uncle Siegfried Mayer, MD, as well as the entire extended Wenig and Urrutia families for their steadfast support and love.

I am indebted to the individuals at Elsevier, including William Schmitt, Kathryn DeFrancesco, Carol

O'Connell, and the entire Elsevier staff for their patience and understanding in awaiting completion of this atlas and for assistance in facilitating the publication of this edition. Thank you.

To Matt Townsend, my "drill sergeant," for the grueling early morning workouts he put me through that allowed me to maintain my physical well-being as well as my sanity in the unique environment of living and working in New York City.

Bruce M. Wenig, MD

Embryology, Anatomy, and Histology of the Sinonasal Tract

NASAL CAVITY

Embryology

- Facial prominences (frontonasal, maxillary, and mandibular) appear around the fourth week of gestation and give rise to the boundaries and structures of the face.
 - Nasal placodes, representing bilateral thickening of the surface ectoderm along the frontonasal prominence, form the nasal pits, which, by growth of the surrounding mesenchyme, become progressively depressed along their length and give rise to the primitive nasal sacs, the forerunners of the nasal cavities.
 - Anterior portion of the nasal cavity is the vestibule, the epithelium of which is ectodermally derived and represents the internal extension of the integument of the external nose.
 - The epithelium lining the nasal cavities proper (Schneiderian membrane) is of ectoderm origin.
 - Nasal septum develops from the merged medial nasal prominences.
 - Regions of continuity between the nasal and oral cavities following rupture of the oronasal membrane develop into the choanae.
 - Conchae (turbinates) develop as elevations along the lateral wall of each nasal cavity.
 - Olfactory epithelia develop in the superior posterior portion of each nasal cavity and differentiate from cells in the ectodermally derived nasal cavity epithelium.
- Frontal and nasal bones form the anterior sloping part.
 - Cribriform plate of the ethmoid bone forms the horizontal part and separates the nasal cavity from the anterior cranial fossa (medial part of floor); this area represents the deepest part of the cavity.
 - Body of the sphenoid bone forms the posterior sloping part.
 - Inferior (floor): majority (75%) is formed by the palatine processes of the maxillary bone, thereby intervening between the oral and nasal cavities; the remainder is formed by the horizontal process of the palatine bone.
 - Lateral: formed in the most part by the nasal surface of the maxilla below and in front, posteriorly by the perpendicular plate of the palatine bone, and above by the nasal surface of the ethmoidal labyrinth separating the nasal cavity from the orbit
 - Along the lateral wall of each nasal cavity are identified three horizontal bony projections: the superior, middle, and inferior conchae; occasionally a small fourth concha is identified above the superior concha and is called the supreme concha.
 - Air spaces or meatuses (superior, middle, and inferior) lie beneath and lateral to the conchae and are named according to the concha immediately above it.
 - Medial: formed by the bony nasal septum entirely formed by the vomer and the perpendicular plate of the ethmoid; the anterior portion of the nasal septum represents the septal cartilage.

Anatomic Borders (Figs. 1-1 and 1-2)

- Nasal cavity is divided into right and left halves by the septum; each half opens on the face via the nares or nostrils and communicates behind with the nasopharynx through the posterior nasal apertures or the choanae.
- Each half of the nasal cavity has the following borders (walls):
 - Superior (roof): slopes downward in front and back and is horizontal in its middle:

Innervation

- Innervation of the mucous membranes of the nose is supplied by the ophthalmic and maxillary branches of fifth (trigeminal) nerve via the pterygopalatine (sphenopalatine) ganglion.
- Olfactory mucous membrane contains the cells of origin of the olfactory nerve fibers, which collect into bundles traversing the cribriform plate and end in the olfactory bulb.

Fig. 1-1. A coronal section through the nasal cavity, viewed from the posterior aspect.

The plane of the section on the right side is more anterior. The normal orifice of the maxillary sinus is shown on the right side and an accessory orifice on the left side. (By permission from Berkovitz BKB, Moxham BJ: *Head and neck anatomy*, London, 2002, Martin Dunitz, Fig. 32-10.)

Fig. 1-2. Lateral wall of the nasal cavity.

The conchae have been removed to show the positions of the ostia of the paranasal sinuses and the nasolacrimal duct. (From Drake RL, Vogl AW, Mitchell AWM: *Gray's anatomy for students*, ed. 3, Philadelphia, 2014, Elsevier.)

Vascular Supply and Lymphatic Drainage

- Arteries and veins:
 - Arterial supply to the nasal cavity comes from several sources including the sphenopalatine branch of the internal maxillary artery (a branch of the external carotid artery), the anterior and posterior ethmoidal artery branches of the ophthalmic artery (a branch of the internal carotid artery), and the facial artery (a branch of the external carotid artery).
 - Veins of the nose parallel the arteries with drainage via the sphenopalatine foramen into the pterygoid plexus and then into the internal jugular vein, via the ophthalmic veins into the cavernous sinus and then into the dural venous sinuses, and via the facial vein into either the internal or external jugular vein.
- Lymphatics:
 - Anterior portion of nose drains to the lymphatics, draining the skin covering the external nose, and pass to the submandibular nodes.
 - Majority of the lymphatics of the nasal cavity drain via the retropharyngeal lymph nodes to the deep cervical lymph nodes.

Histology (Figs. 1-3 and 1-4)

- Nasal vestibule is a cutaneous structure composed of keratinizing squamous epithelium and underlying subcutaneous tissue with cutaneous adnexal structures (hair follicles, sebaceous glands, and sweat glands).
- Mucocutaneous junction (limen nasi) is approximately 1 to 2 cm posterior from the nares and represents the point at which the epithelial surface changes from keratinizing squamous epithelium to a ciliated pseudostratified columnar (respiratory) epithelium including identifiable mucocytes (goblet cells); the respiratory epithelium lines the entire nasal cavity and, as previously detailed, is ectodermally derived.
- Submucosa underlying the epithelium is thin, is noteworthy for the presence of seromucous (minor salivary) glands arranged in distinct lobules, normally contains a mixed inflammatory cell infiltrate, including mature lymphocytes and scattered plasma cells but no lymphoid follicles/aggregates, and has a distinct vascular component consisting of large, thick-walled blood vessels:
 - Vascular structures are particularly prominent along the inferior and middle turbinates and may be mistaken for a hemangioma.
- Nasal septum separates the nasal cavities and includes elastic cartilage and lamellar bone:

- Overlying nasal mucosa is closely apposed to these structures, with the periosteum and perichondrium attached so closely as to constitute a single membrane referred to as mucoperiosteum.
- Along the anterior part of the nasal septum the submucosa is rich in thin-walled blood vessels.
 - Referred to as Little's or Kiesselbach's area
 - Represents a frequent site of nosebleeds
- Nasal cartilage is of the hyaline type and has a bluish, translucent, homogeneous appearance.
- Olfactory epithelium consists of: (see Fig. 1-3)
 - Bipolar, spindle-shaped olfactory neural (receptor) cells composed of myelinated axons penetrating the basal lamina to protrude from the mucosal surface and nonmyelinated proximal processes, which traverse the cribriform plate
 - Columnar sustentacular or supporting cells
 - Rounded basal cells lie on basal lamina
 - Olfactory or Bowman glands in the lamina propria representing purely serous type glands

PARANASAL SINUSES

Embryology

- Paranasal sinuses (maxillary, ethmoid, sphenoid, and frontal) develop as outgrowths of the walls of the nasal cavities and become air-filled extensions of the nasal cavities.
- Maxillary and portions of the ethmoidal sinuses develop during late fetal life, whereas the frontal and sphenoid sinuses, which are not present at birth, develop during the early years of life.

Anatomic Borders (see Fig. 1-1)

- Maxillary sinuses: largest of the paranasal sinuses and located in the body of the maxilla; from above, the maxillary sinus has a triangular shape with the base formed by the lateral wall of the nasal cavity and the apex projecting into the zygomatic arch; borders include:
 - Superior (roof): orbital surface of the maxilla (floor of the orbit)
 - Inferior (floor): alveolar and palatine process of the maxilla
 - Anterolateral: facial surface of the maxilla
 - Posterior: infratemporal surface of the maxilla
 - Medial: lateral wall of the nasal cavity
 - Maxillary ostium (hiatus semilunaris) is on the highest part of the medial wall of the sinus and does not open directly into the nasal cavity but into the posterior ethmoid infundibulum (uncinate groove), which opens into the middle meatus of the nasal cavity.

Fig. 1-3. Sinonasal mucosa.

A, Transitional area from cutaneous portion of nasal vestibule (not shown) to mucosal portion shows the presence of intraepithelial mucocytes and absence of cutaneous adnexal structures; the presence of mucocytes identified the epithelium as being of mucosal (Schneiderian) and not cutaneous origin. **B**, Surface of the entire sinonasal tract is lined by ciliated respiratory epithelium separated from the submucosa by a basement membrane; submucosal seromucous glands are present throughout the sinonasal tract. **C**, Thick-walled vascular structures are normal structures found in the nasal turbinates. **D**, Normal (hyaline) cartilage of the nasal septum. **E**, Mucoperiosteum showing the presence of sinonasal mucosa lying in close apposition to subjacent lamellar bone.

Fig. 1-4. Olfactory mucosa.

A, Spindle-shaped olfactory (neural) cells with microvilli; basal cells lie on the basal lamina; olfactory or Bowman glands in the lamina propria are serous-type glands.

B, Small nerve fibers lie immediately below the olfactory epithelium.

Osteomeatal Complex or Unit

- Not a discrete anatomic structure but refers to a functional unit of structures that include the maxillary sinus ostium, ethmoid infundibulum, hiatus semilunaris, and frontal recess
- Common final pathway for drainage of secretions from the maxillary, frontal, anterior, and middle ethmoid sinuses into the middle meatus
- Obstruction of osteomeatal complex plays pivotal role in development and persistence of sinusitis.
- Coronal high-resolution computed tomography (HRCT) is the preferred imaging modality, providing exquisite detail of these structures.

Ethmoid Sinuses

- Consist of thin-walled cavities in the ethmoidal labyrinth completed by the frontal, maxillary, lacrimal, sphenoidal, and palatine bones varying in size and number, usually consisting of two to eight anterior and middle ethmoid cells and two to eight posterior ethmoid cells.
- Based on the relation to the ethmoid infundibulum the ethmoid cells are grouped into:
 - Anterior group: ostia open directly in relation to the ethmoid infundibulum
 - Middle or bullous group: ostia open on or above the ethmoid infundibulum
 - Posterior group: ostia open into the superior meatus

Frontal Sinuses

- Roughly pyramidal and located in the vertical part of the frontal bone; these sinuses are frequently asymmetric in size and often contain septa subdividing the cavity:
 - Ostia of the frontal sinus opens into the anterior part of the middle meatus.
 - Important anatomic relation includes proximity to the anterior cranial fossa and orbit separated only by a thin plate of bone from these structures.

Sphenoid Sinuses

- Contained within the sphenoid bone situated posterior to the upper part of the nasal cavity:
 - Related above to the optic chiasm and the hypophysis cerebri
 - Related on each side to the internal carotid artery and cavernous sinus
 - Opens into the sphenoethmoidal recess lying above and behind the superior nasal concha

Innervation

- Maxillary sinuses
 - Innervation supplied by the maxillary branches of fifth (trigeminal) nerve, including the anterior, middle, and posterior superior alveolar nerves and the infraorbital nerve
- Ethmoid sinuses
 - Innervation supplied by the ophthalmic and maxillary branches of fifth (trigeminal) nerve, including the nasociliary, anterior ethmoid, and posterior ethmoid nerves and the orbital branches of the pterygopalatine (sphenopalatine) ganglion
- Frontal sinuses
 - Innervation supplied by the supraorbital and supratrochlear branches of the frontal nerve, a

derivative of the ophthalmic branch of fifth (trigeminal) nerve

- Sphenoid sinuses
 - Innervation supplied by the ophthalmic and maxillary branches of fifth (trigeminal) nerve, including the posterior ethmoid nerve and the orbital branches of the pterygopalatine (sphenopalatine) ganglion

Vascular Supply and Lymphatic Drainage

Arteries and Veins

- Maxillary sinuses
 - Major blood supply comes from branches of the maxillary artery (infraorbital, greater palatine, postero- and anterosuperior alveolar arteries and sphenopalatine artery) with smaller contribution from the facial artery; the maxillary and facial arteries are branches of the external carotid artery.
 - Venous drainage occurs anteriorly via the anterior facial vein to the jugular vein and posteriorly via the maxillary vein to the jugular system by way of the retromandibular vein; in addition, in the region of the infratemporal fossa, the maxillary vein communicates with the pterygoid venous plexus, which anastomoses with the dural sinuses through the base of the skull.
- Ethmoid sinuses
 - Receives its blood supply from the internal and external carotid arteries via branches of the ophthalmic (anterior and posterior ethmoidal arteries) and maxillary (nasal branch of sphenopalatine artery) arteries, respectively
 - Venous drainage occurs by two routes:
 - Into the nose via the nasal veins, which flow to the maxillary vein and then retromandibular vein and ultimately into the external jugular vein
 - Via the ethmoidal veins to the ophthalmic veins to the cavernous sinus
- Frontal sinuses
 - Receives its blood supply from branches of the ophthalmic artery (supraorbital and supratrochlear arteries), a branch of the internal carotid artery
 - Venous drainage is to the cavernous sinus by way of the superior ophthalmic vein.
- Sphenoid sinuses
 - Receives its blood supply from the internal and external carotid arteries via branches of the oph-

thalmic (posterior ethmoidal artery) and maxillary (sphenopalatine artery) arteries, respectively

- Venous drainage occurs to the maxillary vein, which flows to the external jugular vein by way of the retropharyngeal vein and to the pterygoid plexus, which flows to the facial vein, which empties into the internal jugular vein.

Lymphatics

- Maxillary sinuses
 - Lymphatic drainage is to the submandibular lymph nodes.
- Ethmoid sinuses
 - Lymphatic drainage occurs to the submandibular (from the anterior and middle ethmoid groups) and the retropharyngeal (from posterior ethmoid group) lymph nodes.
- Frontal sinuses
 - Lymphatic drainage occurs to the submandibular lymph nodes.
- Sphenoid sinuses
 - Lymphatic drainage occurs to the retropharyngeal lymph nodes.

Histology (see Fig. 1-1)

- All of the sinuses are lined by ciliated pseudostratified, columnar epithelium including identifiable mucocytes (goblet cells) and together with the nasal cavity are referred to as the Schneiderian membrane:
 - Schneiderian epithelium is ectodermally derived in contrast with the similar appearing epithelium lining the nasopharynx, which is of endodermal derivation.
- Although the epithelia of the paranasal sinuses is the same as that of the nasal cavity, the mucous membranes of the paranasal sinuses are thinner and less vascular than those of the nasal cavity and have a fibrous layer adjacent to the periosteum.
- Seromucous glands are scattered throughout the paranasal sinus submucosa, particularly seen in the ostial areas.

Non-Neoplastic Lesions of the Sinonasal Tract

CLASSIFICATION OF NON-NEOPLASTIC LESIONS OF THE SINONASAL TRACT (Box 2-1)

BOX 2-1 Classification of Non-Neoplastic Lesions of the Sinonasal Tract

- Rhinosinusitis
- Sinonasal polyps:
 - Nasal (inflammatory) polyps
 - Antrochoanal polyp
- Paranasal sinus mucocele
- Heterotopic central nervous system tissue and encephalocele
- Nasal dermoid sinus and cyst
- Hamartomas:
 - Respiratory Epithelial Adenomatoid Hamartoma (REAH)
 - Chondro-osseous and respiratory epithelial (CORE) hamartoma
 - Nasal chondromesenchymal hamartoma
- Infectious diseases:
 - Fungal (fungal sinusitis, others)
 - Bacterial (rhinoscleroma, others)
 - Protozoal (leishmaniasis, others)
 - Viruses
- Sarcoidosis
- Myospherulosis
- Extranodal sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman disease)
- Vasculitides (e.g., granulomatosis with polyangiitis; Churg-Strauss disease)
- Necrotizing sialometaplasia
- Eosinophilic angiocentric fibroma
- IgG4-related diseases
- Others

RHINOSINUSITIS (Figs. 2-1 through 2-6)

Definition: Nonspecific or specific inflammation of the sinonasal tract that may be isolated to the nasal cavity (rhinitis), isolated to the paranasal sinuses (sinusitis), or involve nasal cavity and paranasal sinuses (rhinosinusitis).

Clinical

- Causes of rhinosinusitis are numerous (Box 2-2) and include:
 - Allergic (most common)

BOX 2-2 Causes of Rhinosinusitis

- Allergic (most common)
 - Infectious
 - Aspirin intolerance
 - Nonallergic rhinosinusitis with eosinophilia (NARES)
 - Idiopathic
 - Occupational or environmental exposure
 - Systemic diseases
 - Structural or mechanical causes
 - Medication-induced
 - Pregnancy
-
- Infectious
 - Aspirin intolerance
 - Nonallergic rhinosinusitis with eosinophilia (NARES)
 - Idiopathic
 - Occupational or environmental exposure
 - Systemic diseases
 - Structural or mechanical causes:
 - Deviated nasal septum
 - Neoplasms
 - Immotile cilia syndrome
 - Medication-induced:
 - Referred to as rhinosinusitis medicamentosa
 - May be caused by topical or systemic medications, such as:
 - Propranolol, oral contraceptives, reserpine, others
 - Nasal sprays
 - Pregnancy:
 - Thought to result from the combined effects on the nasal mucosa by pregnancy-related hormones, increased blood volume, and airway resistance
-
- Often the diagnosis of rhinosinusitis is straightforward by clinical evaluation and does not require radiographic imaging or tissue sampling; however, there are exceptions in which radiographic imaging and biopsies are required to establish a diagnosis of rhinosinusitis and to exclude other possible diseases that cause and/or are associated with rhinosinusitis.

Allergic Rhinosinusitis

- In adults, allergies are the most common cause of rhinosinusitis.

Fig. 2-1. Acute bacterial sinusitis.

Axial contrast-enhanced CT scans of three different patients. **A**, Enhancement of the inflamed mucosa within the left maxillary sinus. There is a zone of water attenuation separating this mucosa from the bony wall of the sinus. This zone is submucosal edema. There are also water attenuation secretions within the sinus cavity that represent increased surface secretions from the inflamed mucosa. This is the typical picture of sinus inflammation. **B**, Inflammation within the right maxillary sinus. In this case, there is more submucosal edema and a smaller amount of secretions than in **A**.

C, Inflammation within the left maxillary sinus. In this case, there is little submucosal edema and a large amount of surface secretions. These three cases illustrate the variations in reactions to inflammation. They do not predict outcome.

(From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, 2011, p 168, Fig. 3-2.)

Fig. 2-2. Acute bacterial sinusitis.

Axial CT scan (**A**) shows an air-fluid level in the right antrum. The attenuation of this fluid is less than that of muscle and typically is watery sinus secretions. This could represent an acutely obstructed sinus, a sinus with poor drainage in a chronically supine (unconscious) patient, or a patient who had a recent antral washing for sinusitis. Coronal CT scan (**B**) shows a typical air-fluid level in the left antrum with minimal mucosal thickening and obstruction of the ostiomeatal unit. Some mucosal disease is also present in the left ethmoid and right maxillary sinuses. Clinically, this patient had acute sinusitis. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, 2011, p 174, Fig. 3-10.)

Fig. 2-3. Chronic bacterial sinusitis.

Axial T2-weighted MR image (**A**) shows apparent right-sided minimal, scattered mucosal thickening in the ethmoid and sphenoid sinuses. Axial CT scan (**B**) on the same patient as in **A** and performed on the same day shows opacification of the left ethmoid and sphenoid sinuses. Centrally within most sinuses is higher attenuation material representing either desiccated secretions or fungal mycetomas. This patient had chronic bacterial sinusitis. These images illustrate how MR may underestimate the amount of disease in some cases. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 179, Fig. 3-18.)

Fig. 2-4. Chronic sinusitis.

Axial T1-weighted (**A**) and T2-weighted (**B**) MR images show what appears to be moderate ethmoid sinusitis with residual aeration in scattered right ethmoid cells and in the right sphenoid sinus. In a CT scan (**C**), these sinuses are completely opacified, with desiccated secretions that are separated from the sinus walls by a thin zone of mucoïd attenuation. This patient had chronic sinusitis. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 200, Fig. 3-19.)

Fig. 2-5. Chronic sinusitis.

Axial T1-weighted (**A**) and T2-weighted (**B**) MR images show expansion of the ethmoid complexes, with apparently moderate mucosal thickening in the ethmoid sinuses. The sphenoid sinuses appear aerated. However, a CT scan (**C**) shows that the expanded ethmoid and sphenoid sinuses are totally opacified, with desiccated secretions. This patient had chronic sinusitis. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 201, Fig. 3-20.)

- In children, allergies represent the second most common cause of rhinosinusitis second to viral upper respiratory infection.
- No gender predilection; occurs over a wide age range
- Caused by exposure to allergen in sensitized patient and mediated via type I IgE immune reaction:
 - Among the more common allergens are pollens, animal dander, dust mites, mold.
- May predispose patients to recurrent or chronic sinusitis
- May be familial
- In a sensitized patient, exposure results in allergic reaction that produces nasal congestion with rhinorrhea, sneezing, and itching:
 - In noninfected patients, the nasal secretions appear clear.
 - In infected patients, the nasal secretions appear purulent.
 - The reaction begins within minutes of exposure, peaking about 15 minutes later.
- The endoscopic appearance of the sinonasal mucosa is pale to bluish; inflammatory polyps may or may not be identified.
- Generally, the standard for allergy testing is considered to be skin testing:
 - Represents a reaction between antigen and sensitized mast cells in the skin, causing a wheal and flare skin response
 - Occasionally may be negative in allergic rhinosinusitis patients because of local (nasal) synthesis of IgE with the local (nasal) tissue being more sensitive than the distant (cutaneous) site
- Histopathologic findings include submucosal edema with a mixed inflammatory cell reaction dominated by the presence of eosinophils:
 - Squamous metaplasia of the surface epithelium may be present.
 - Neutrophils can be identified, especially in the presence of secondary bacterial infection.
- Treatment includes antihistamines, nasal cromolyn preparations (stabilizes mast cells against

Fig. 2-6. Nonspecific chronic sinusitis.

A and B, The histopathologic changes include submucosal mixed inflammation, including mature lymphocytes with a variable admixture of plasma cells, eosinophils, histiocytes and neutrophils, and edema. **C and D,** Squamous metaplasia of the surface epithelium (normally a ciliated respiratory epithelium) is often present that may also include sialometaplasia (squamous metaplasia of seromucous glands; lower right in **D**). **E and F,** Secondary alterations that may occur in long-standing cases of chronic sinusitis include prominent papillary architecture composed of ciliated pseudostratified columnar epithelial cells with intermixed goblet cells. This appearance is clinically referred to hyperplastic papillary sinusitis.

degranulation and release of inflammatory mediators), topical corticosteroids, immunotherapy for documented IgE-mediated allergies.

Infectious Rhinosinusitis

- Caused by a variety of microorganisms, the most common of which are viruses and bacteria
- No gender predilection; occurs over a wide age range
- Viral rhinosinusitis results in the “common cold”:
 - Symptoms include nasal congestion and a watery nasal discharge.
 - Among the more common viruses implicated in causing disease are rhinoviruses, influenza and parainfluenza viruses, adenoviruses, and respiratory syncytial virus.
 - May be secondarily infected by bacteria manifested by a mucopurulent discharge
 - Usually self-limiting disease course
- Bacterial sinusitis:
 - Among the more common bacteria implicated in causing disease include *Streptococcus pneumoniae*, *Haemophilus influenzae*, and α -hemolytic streptococci.
 - Associated with pain localized over infected site; headaches are uncommon.
 - May be acute, subacute, or chronic:
 - Acute:
 - Persistent and worsening symptoms longer than 7 days but less than 3 weeks
 - Subacute:
 - Symptoms lasting 3 weeks to 3 months
 - Chronic:
 - Symptoms last more than 3 months
 - Patients with resistant or refractory chronic sinusitis have increased incidence of *Staphylococcus aureus*, anaerobic bacteria, gram-negative organisms.
 - *Pseudomonas aeruginosa* is a commonly cultured organism in patients who have received multiple courses of antibiotics over extended periods of time.
 - The culturing of *Pseudomonas* sp. suggests an immune deficiency condition.
 - Appropriate antibiotic therapy is curative.

Atrophic Rhinosinusitis

- Also referred to as “ozena” (stench) and occasionally “rhinitis sicca”
- More common in women; begins in childhood often in the second decade of life at the onset of puberty
- Characterized by atrophy of the nasal mucosa, crust formation, and foul-smelling odor from the nasal cavity
- Caused by a variety of factors, including:
 - Chronic bacterial infection
 - Nutritional (e.g., vitamin A, iron) deficiencies

- Chronic exposure to irritants
- Prior radiation or surgery
- End stage of chronic infections
- Hypoestrogenemia
- Autoimmune disease
- Symptoms include nasal obstruction, headaches, nasal crusting, anosmia, epistaxis, halitosis, and foul-smelling nasal odor.
- Histologically, biopsies show various degrees of squamous metaplasia of the mucosal surface epithelium, submucosal edema with nonspecific chronic inflammation, fibrosis, and atrophic and decreased numbers of seromucous glands and vascular dilatation:
 - The histologic findings are nonspecific.
 - The clinical impression of the atrophic appearance of nasal cavity tissues (e.g., turbinates) is important in trying to make the diagnosis.
 - Excluding evidence of other possible diseases is necessary.
- Medical therapy (e.g., antibiotics, nutritional supplements [vitamin A, iron, estrogen], and surgery) has been used to treat atrophic rhinosinusitis.
- No known cure; over time, the active disease may spontaneously arrest with disappearance of the nasal crusting and foul odor.

Aspirin Intolerance or Aspirin-Exacerbated Respiratory Disease (AERD)

- Also referred to as Samter triad or syndrome, which includes:
 - Aspirin intolerance
 - Sinonasal polyps
 - Asthma
- No gender predilection; often begins in the third to fourth decades of life
- Within hours of aspirin ingestion, patients may experience bronchoconstriction and rhinorrhea:
 - In some patients may also follow ingestion of nonsteroidal antiinflammatory medications
 - Symptoms may also include nausea, vomiting, diarrhea with gastrointestinal cramping.
 - Considered to be a pharmacologic effect with interference in the metabolism of arachidonic acid rather than an allergic response
- Polyps usually are bilateral:
 - Histology of polyps is similar to that of sinonasal inflammatory polyps not occurring in aspirin-intolerant patients.
- Presence of nasal polyps has a significant negative impact on patients with chronic rhinosinusitis:
 - Patients with nasal polyps have more severe symptoms with less improvement after operative intervention and a significantly higher need for revision surgery.

- Nonallergic rhinosinusitis with eosinophilia (NARES) syndrome may be precursor to the aspirin intolerance syndrome.
- Treatment includes:
 - Avoidance of instigating medications
 - Symptomatic relief
 - Polypectomy

Radiology of Rhinosinusitis

Acute Rhinosinusitis

- Air-fluid levels represent the best diagnostic clue characterized by bubbly appearing secretions within a sinus and mucosal thickening:
 - Most common in ethmoid and maxillary sinuses
 - Creates a “foam on water” appearance
 - Sinus lumen size remains normal without expansion or reduction in volume:
 - Sinus expansion can be seen in mucocoeles.
 - Sinus reduction in volume can be seen with chronic rhinosinusitis.
 - Not accurate in assessing extent of inflammation
- CT findings:
 - Peripheral soft tissue mucosal thickening within sinus
 - Inflammatory tissue obstructing drainage pathways of osteomeatal complex
 - Contrast-enhanced CT shows enhancement of inflamed mucosa but not central secretions.
- MR findings:
 - Not frequently performed for rhinosinusitis
 - Used to evaluate for orbital and intracranial complications
 - Can be used to differentiate fungal from other inflammatory diseases
 - Can be used to differentiate inflammatory lesions from neoplasms

Chronic Rhinosinusitis

- Mucosal thickening or soft tissue opacification of nonexpanded sinus with thickening and sclerosis of sinus bony walls:
 - Most common in ethmoid sinus followed by maxillary sinuses, frontal and sphenoid sinuses
 - Sinus lumen size remains normal or is decreased in volume.
- CT findings:
 - Mucosal thickening or opacification of sinus without sinus expansion
 - Variable density (isodense to hyperdense) of secretions depending on content (protein, water, fungi)
 - Better at detecting luminal sinus disease than endoscopic evaluation

- Lack of correlation between symptomatology and imaging findings

Pathology of Nonspecific Chronic Rhinosinusitis

Histology

- The histologic changes of nonspecific chronic sinusitis include:
 - Submucosal mixed inflammatory cell infiltrate, including mature lymphocytes with variable admixture of plasma cells, eosinophils, histiocytes, and neutrophils
 - Submucosal edema
 - Surface mucosa squamous metaplasia is often (but not uniformly) present.
 - Minimal fibrosis
 - Vascular proliferation may be present
 - In long-standing and/or recurrent/persistent disease, inflammatory epithelial hyperplasia may be present, characterized by:
 - Papillary appearance to the surface mucosa
 - Epithelium is bland appearing, lined by single layer of columnar cells and goblet cells.
 - Abundant inflammatory cells within lamina propria
 - May be referred to clinically as (hyperplastic) papillary sinusitis

Differential Diagnosis

- A more specific cause of sinusitis (see previous and subsequent sections)
- Sinonasal inflammatory polyp
- Neoplastic proliferation especially in the setting of inflammatory epithelial hyperplasia

Treatment and Prognosis

- Rhinosinusitis is a spectrum of diseases, and defining its various subtypes will alter management to include medical treatment (e.g., steroids, antibiotics) and surgery (e.g., functional endoscopic sinus surgery [FESS]).
- Management often involves combination of systemic and topical therapies, with surgery reserved for patients who fail medical therapy.
- FESS is among the most common surgeries performed for sinonasal disease refractory to maximal medical therapy.
- Optimal timing of FESS in treatment remains to be defined.
- Over the past decades, the average life expectancy for patients with cystic fibrosis has increased; with increasing survival and improved pulmonary management, otolaryngologists are now seeing increasing numbers of cystic fibrosis patients with chronic rhinosinusitis:

- For adult and pediatric cystic fibrosis patients with sinusitis, endoscopic sinus surgery yields clinical improvement measured primarily by sino-nasal symptoms and endoscopic findings.
- In general, sinusitis is not life threatening but depending on cause may result in ongoing and persistent morbidity.

SINONASAL INFLAMMATORY POLYPS (Figs. 2-7 through 2-12)

Definition: Non-neoplastic inflammatory swellings of the sinonasal mucosa.

Clinical

- No gender predilection; occur in all ages but are commonly seen in adults over 20 years of age and rarely seen in children less than 5 years of age:
- The exception to this age restriction occurs in patients with cystic fibrosis, who develop nasal polyps in the first and second decades of life.
- Most polyps arise from the lateral nasal wall or from the ethmoid recess; not infrequently, involvement of the nasal cavity and paranasal sinuses occurs:
 - Common occurrence along the lateral nasal wall probably relates to the fact that the normal physiologic parameters of lateral nasal cavity mucosa are such that prominent edema readily forms in the mucosal lamina propria.
- Polyps may be unilateral or bilateral, single or multiple.
- Symptoms include nasal obstruction, rhinorrhea, and headaches:
 - The triad of nasal polyps, asthma, and aspirin intolerance is well recognized and is referred to as Samter's triad.

Fig. 2-7. Sinonasal inflammatory polyp.

Axial contrast-enhanced CT scans (**A, B**) and coronal CT scan (**C**) show bilateral nasal masses that have displaced the nasal bones anterolaterally and thinned part of the nasal septum. The upper nasal fossae are widened by the nasal masses, and the medial aspect of the each ethmoid complex has been displaced laterally. There are also inflammatory changes in the ethmoid, sphenoid, and maxillary sinuses. This patient had nasal polyposis and sinusitis. Axial CT scan (**D**) on another patient shows that nasal polyposis has widened the upper nasal cavity by pushing the medial ethmoid complex walls laterally (arrows). Inflammatory disease also is seen in the sphenoid sinuses in this patient with allergic sinusitis and polyposis. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 199, Fig. 3-49.)

**Fig. 2-8.**

Endoscopic appearance of sinonasal inflammatory polyps appearing as multiple polypoid masses with a glistening mucoid appearance.

- Radiology:
 - Soft tissue densities, air-fluid levels, mucosal thickening, and opacification of the paranasal sinuses; when extensive, inflammatory polyps may expand and even destroy bone.
- Cause is linked to multiple factors, including allergy (atopy), infections, cystic fibrosis, diabetes mellitus, and aspirin intolerance.
- Mulberry turbinate is a clinical term that refers to swollen nasal turbinate tissue formed as a result of edema interspersed among the thick vessel walls of the prominent (essentially normal) turbinate vascularity; this appearance may clinically suggest a pathologic process such as a vascular malformation.

Pathology

Gross

- Sinonasal polyps are soft, fleshy, polypoid lesions with a myxoid or mucoid appearance.
- Polyps vary in size, ranging up to several centimeters in diameter.

Histology

- Surface epithelium is composed of intact respiratory epithelium but may show squamous metaplasia; the basement membrane may be thickened and eosinophilic in appearance.

**Fig. 2-9.**

Transected sinonasal inflammatory polyp appearing as tan-white, polypoid-shaped tissue with a shiny, myxoid/mucoid appearance.

- Stroma is markedly edematous and is noteworthy for the absence of seromucous glands; a mixed chronic inflammatory cell infiltrate is present and is predominantly composed of eosinophils, plasma cells, and lymphocytes; neutrophils may predominate in polyps of infectious origin.
- Stroma contains bland-appearing fibroblasts and small to medium-sized blood vessels.
- Secondary changes include surface ulceration, fibrosis, infarction, granulation tissue, deposition of an amyloid-like stroma, osseous and/or cartilaginous metaplasia, glandular hyperplasia, granuloma formation, and atypical stromal cells:
 - Granulomas result from ruptured mucous cysts, cholesterol granulomas, or as a reaction to medicinal intranasal injections (steroids) or inhalants.
- Occasionally small patches of stromal nonedematous collagen may be found scattered in a polyp that

Fig. 2-10. Histologic features of sinonasal polyps.

A, Polypoid-appearing mass with intact surface (respiratory) epithelium with the underlying stroma characterized by edema, inflammatory infiltrate, and variable vascularity. **B**, Seromucous glands are typically absent but may be present and appear dilated (ecstatic), filled with mucinous material. **C**, The inflammatory infiltrate includes an admixture of lymphocytes, plasma cells, eosinophils, and neutrophils. **D**, Intact surface ciliated respiratory epithelium overlying an edematous stroma with associated chronic inflammation and thin-walled vascular spaces. **E**, In this patient's inflammatory polyp, an incidentally identified focus of high-grade intraepithelial dysplasia (i.e., carcinoma in situ) was focally identified. This is an extraordinarily rare occurrence. **F**, This focus of high-grade intraepithelial dysplasia shows increased proliferation rate by Ki67 staining throughout the epithelium. There was no immunoreactivity for p16 (not shown).

Fig. 2-11. Sinonasal inflammatory polyp.

A, Similar to the polyp depicted in Fig. 2-9, this polyp is pedunculated with a glistening appearance but had firmer consistency owing to increased fibrosis. **B**, Histologically, there is increased stromal fibrosis, a secondary (chronic) reactive alteration.

Fig. 2-12. Sinonasal inflammatory polyp with atypical stromal cells.

A, There is an increased number of inflammatory cells, including spindle-shaped and pleomorphic cells, which have been referred to as atypical stromal cells. **B**, The atypical stromal cells are myofibroblasts characterized by large vesicular-appearing nuclei with identifiable nucleoli and abundant cytoplasm with a basophilic and fibrillar appearance. **C**, In some examples the myofibroblasts can be disturbing in their appearance characterized by enlarged hyperchromatic nuclei raising concern for a malignant cellular infiltrate (e.g., rhabdomyoblasts); note the presence of ample amount of cytoplasm (low nuclear-to-cytoplasmic ratio) often seen in these cells and a feature that would support benignancy, albeit with atypical features.

may have inflammatory cells aggregated around its periphery, creating a “pseudogranuloma.”

- Stroma may have spaces containing a watery-appearing fluid and simulate the appearance of lymphatic spaces, which may suggest a diagnosis of lymphangioma; however, these spaces lack an endothelial cell lining.
- Atypical stromal cells (ASC) can be seen in sinonasal and antrochoanal polyps but tend to be more common in the latter:
 - ASC are bizarre-appearing cells with enlarged, pleomorphic, and hyperchromatic nuclei, indistinct to prominent nucleoli, and eosinophilic- to basophilic-appearing cytoplasm; typically, an ample amount of cytoplasm is present so that there is a low nuclear-to-cytoplasmic ratio, a feature usually associated with benignancy.
 - ASC tend to cluster near areas of tissue injury (e.g., near thrombosed vascular spaces).
 - ASC may be confused with malignant cells (e.g., rhabdomyoblasts), but their localization to limited areas of the lesion coupled with the absence of an increased nuclear-to-cytoplasmic ratio, increased mitoses, atypical mitoses, or cross-striations should preclude a diagnosis of malignancy.
 - ASC are of myofibroblastic origin and likely represent a component of wound healing.
 - Immunohistochemical staining of ASC may include reactivity for:
 - Vimentin, actins (smooth muscle and muscle specific), and cytokeratins; the presence of cytokeratin reactivity may result in the suggestion of a spindle cell squamous carcinoma (sarcomatoid carcinoma), but the overall histology points to an inflammatory polyp and not an epithelial malignancy.
 - No immunoreactivity for desmin, myoglobin, myogenin (myf4)
- Prominent vascular component, variably termed angiomatous or angioectatic nasal polyps, may clinically and histologically simulate a malignant tumor:
 - These lesions may undergo infarction or be associated with acellular eosinophilic material simulating amyloid deposition; Congo red staining is negative.
 - Papillary endothelial hyperplasia may be present.
- An extremely rare occurrence that may be seen in association with sinonasal inflammatory polyps (as well as in nonspecific chronic sinusitis) may be the presence of incidentally identified foci of intraepithelial high-grade dysplasia:
 - Such examples occur in the absence of invasive carcinoma.
 - Such examples are limited in extent, usually only focally identified in the resected tissue(s).

- Other than close clinical follow-up, there is no need for additional treatment if these foci of high-grade intraepithelial dysplasia are limited in extent.

Differential Diagnosis

- Infectious diseases (tuberculosis, sarcoid, others)
- Schneiderian papilloma:
 - May occur in the background of histologic changes of a sinonasal inflammatory polyp or, similar to sinonasal inflammatory polyps, may have marked stromal edema
 - Surface epithelial proliferation seen in association with Schneiderian papillomas is absent in inflammatory polyps.
- Nasopharyngeal angiofibroma (NPAF):
 - Histologic features including slit-like vessels lacking significant smooth muscle component and variably cellular fibrous stroma absent in sinonasal inflammatory polyps
- Sinonasal hamartomas (e.g., respiratory epithelial adenomatoid hamartoma, seromucinous hamartoma, others): see later in this section
- Heterotopic central nervous system tissue (HCNST) and acquired encephalocele:
 - Brain tissue in the setting of HCNST and acquired encephalocele may be histologically altered and/or associated with fibrotic tissue and may not readily be recognized as CNS tissue.
 - HCNST and acquired encephaloceles can be mistaken for inflammatory polyps.
 - Immunostains including GFAP may be required to assist in identifying CNS type tissue.
- Granulomatosis with polyangiitis (formerly known as Wegener granulomatosis)
- Squamous intraepithelial lesions (i.e., dysplasia, carcinoma in situ):
 - Rarely occurs as an isolated finding in the sinonasal tract in the absence of a coexisting invasive carcinoma
- Rhabdomyosarcoma (due to the presence of atypical stromal cells, which may be confused with rhabdomyoblasts; see Antrochoanal Polyp)
- Amyloidosis

Treatment and Prognosis

- Identification and treatment of possible etiologic factor(s) is the initial approach in the treatment of sinonasal polyps.
- Surgical excision includes polypectomy for nasal polyps and medial maxillectomy (Caldwell–Luc procedure) to include removal of the stalk for antrochoanal polyps.
- Approximately 50% of patients will have recurrence of their nasal polyps following surgery, recurrence

rates being highest in patients with aspirin intolerance and asthma.

- Development of functional endoscopic sinus surgery (FESS) has contributed to decreasing the morbidity of sinonasal surgery and the recurrence of nasal polypoidosis in patients with cystic fibrosis and in improving sinonasal-related symptomatology for patients with asthma.
- Sinonasal inflammatory polyps occurring in patients with cystic fibrosis may respond to medical therapy, but surgical resection may be required.
- Systemic steroid treatment effective in decreasing polyp size and in controlling mucosal inflammation:

- Steroid treatment results in decrease in nasal symptoms and polyp size.
- Systemic steroid treatment may also contribute to prevention of recurrence.

ANTROCHOANAL POLYP

(Figs. 2-13 through 2-16)

Definition: Clinically distinctive variant of sinonasal inflammatory polyp originating from within the maxillary sinus (medial wall area) and extending via a stalk through the ostium of the maxillary sinus into the nasal cavity; most of the growth occurs in the nasal cavity.

Synonym: Killian polyp

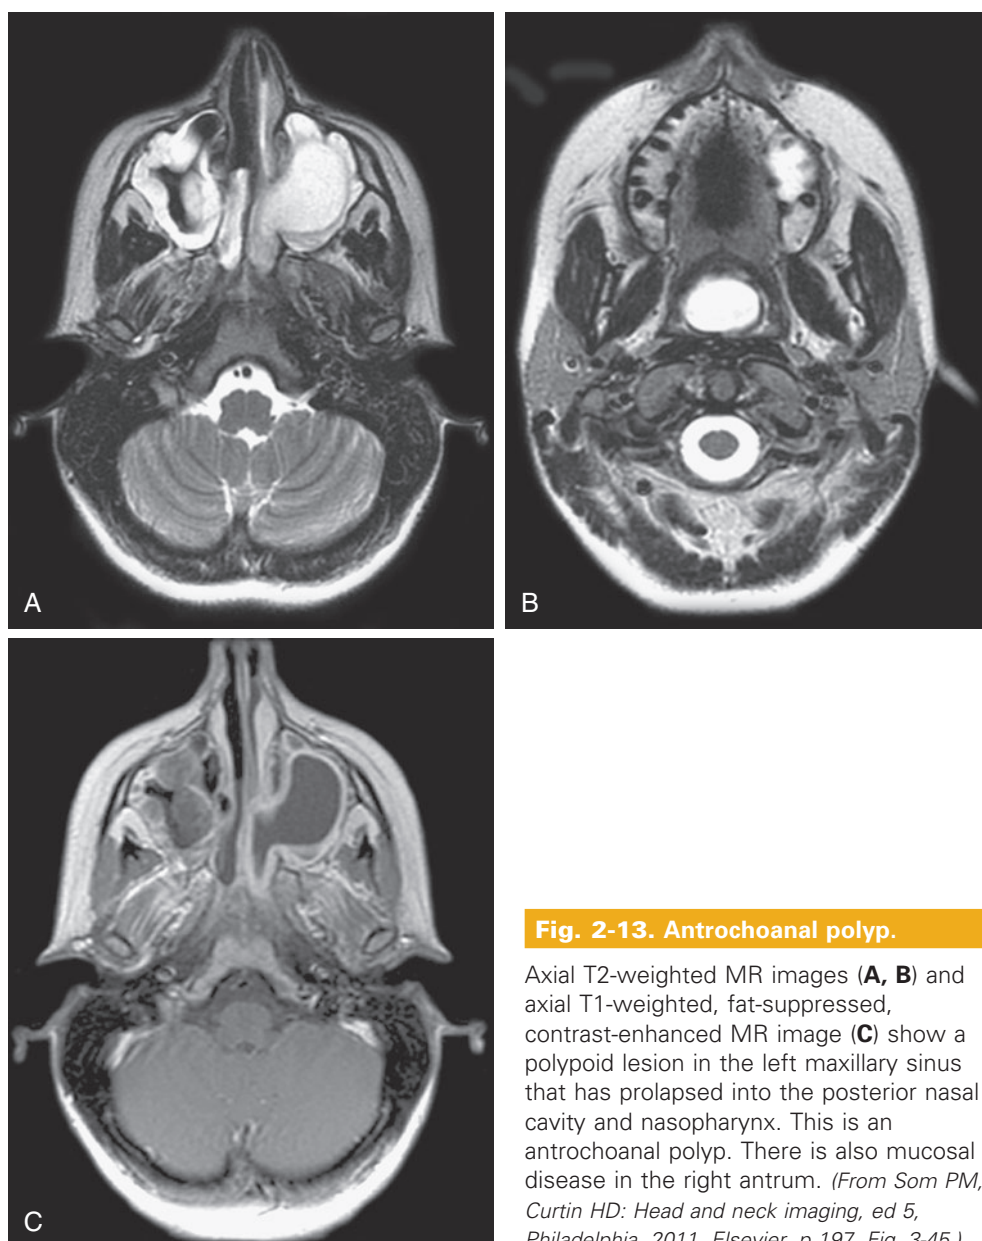

Fig. 2-13. Antrochoanal polyp.

Axial T2-weighted MR images (**A, B**) and axial T1-weighted, fat-suppressed, contrast-enhanced MR image (**C**) show a polypoid lesion in the left maxillary sinus that has prolapsed into the posterior nasal cavity and nasopharynx. This is an antrochoanal polyp. There is also mucosal disease in the right antrum. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 197, Fig. 3-45.)

**Fig. 2-14.**

Antrochoanal polyp appearing as polypoid mass of tan-pink tissue filling the nasal cavity grossly indistinguishable from other sinonasal polyps.

**Fig. 2-15.**

Resected antrochoanal polyp characterized by the presence of a pedicle generally absent from nonchoanal-derived sinonasal inflammatory polyps.

Clinical

- Represents approximately 3% to 6% of all sinonasal polyps
- More common in men than in women; tend to occur in patient populations that are younger (i.e., teenagers and young adults) as compared to patient population affected by nasal polyps
- Generally present as a single, unilateral polyp with nasal obstruction; however:
 - Posterior extension from the maxillary sinus toward the nasopharynx may result in obstruction of the nasopharynx and clinical suspicion of a primary nasopharyngeal tumor.
 - May extend (“hang”) into the oropharynx and be identifiable through the open mouth
- Often associated with bilateral maxillary sinusitis, and despite correlation in up to 40% of cases of associated allergies, the antrochoanal polyp is felt to be of an inflammatory cause.
- Antrochoanal polyps are often associated with bilateral maxillary sinusitis and may also be associated with more typical sinonasal polyps:

- Sphenchoanal polyps originate from the sphenoid sinus and extend through the sphenoid ostium, across the sphenothmoid recess, and into the choana (the boundary between the nasal cavity and nasopharynx):
 - Rarely, antrochoanal polyp may coexist with sphenchoanal polyp.
- In up to 40% of cases of antrochoanal polyps, there may be a documented history of allergies.
- Radiology:
 - Soft tissue density in the posterior choanal region or in the nasopharynx with clouding or opacification of the maxillary sinus

Pathology

Gross

- Identical to other nasal polyps except for the presence of a stalk with attachment to the maxillary sinus

Histology

- Similar to sinonasal polyps except for a relative lack of mucous glands and an eosinophilic inflammatory infiltrate
- Fibrotic stroma often present
- Because antrochoanal polyps extend via a stalk through the maxillary sinus ostium, a relatively small opening, these polyps often are subject to secondary changes resulting from chronic or subacute vascular compromise, including:
 - Presence of atypical stromal cells identical (in distribution and appearance) to those seen in sinonasal inflammatory polyps (see above)
 - Vascular thrombosis often is present:
 - Atypical stromal cells often cluster around thrombosed blood vessels.
 - Infarction, partial or complete:
 - Hemorrhage in the setting of infarction may be minimal or extensive.
 - Presence of hemorrhage and reactive changes may result in bone erosion of the lateral nasal cavity-medial maxillary sinus wall, which can be extensive.
 - Radiographic features of this process may raise the clinical concern for a malignant neoplasm.
 - Histologically, due to the presence of reactive changes, which may include extensive neovascularization, characterized by multiple, variably dilated vascular channels, confusion with a vascular neoplasm may arise; the presence of prominent neovascularization may be referred to or diagnosed as (pseudo)angiomatic polyp.
 - Papillary endothelial hyperplasia may occur in this setting in conjunction with organizing thrombus.

**Fig. 2-16.**

Antrochoanal polyp, owing to torsion in its passage through the antrum, often has associated reactive and degenerative changes. **A**, Polypoid mass with surface ulceration and associated granulation tissue-like reaction in the submucosa; there is squamous metaplasia of the surface epithelium along the lower portion of the image. **B**, Edema, hemorrhage, and vascular thrombosis may be present; although not shown, necrosis may be part of this histologic picture. **C**, Atypical stromal cells (i.e., myofibroblasts) tend to cluster in areas of injury as is seen here near to a thrombosed vascular space. **D**, Despite their atypical appearance, including hyperchromatic nuclei, myofibroblasts have a low nuclear-to-cytoplasmic ratio, have a fibrillar-appearing cytoplasm, are elongated with axonal-like extensions, and lack atypical mitoses. **E** and **F**, Reactive changes in antrochoanal (and other) polyps may also include papillary endothelial hyperplasia, which may suggest the presence of a vascular neoplasm.

Differential Diagnosis

- Nasopharyngeal angiofibroma
- Vascular proliferation/neoplasm:
 - Hemangioma
 - Angiosarcoma

Treatment and Prognosis

- Cured following complete surgical excision
 - Endoscopic approach for complete removal considered safe and effective procedure
 - A focus on the detection of the exact origin and the extent of the polyp considered key to prevent recurrence
- May recur if the polyp including the stalk is incompletely excised:
 - High recurrence rate also occurs in antrochoanal polyps, especially in patients with a history of allergies.
 - Endoscopic removal may result in a higher recurrence rate.
 - Surgical removal of the polyp with its stalk markedly decreases the likelihood of recurrence.
 - To prevent incomplete excision and recurrences, combined approaches (functional endoscopic sinus surgery and mini-Caldwell) have been advocated.

PARANASAL SINUS MUCOCELE

(Figs. 2-17 through 2-20)

Definition: A distinct clinicopathologic entity in which there is expansion of a sinus cavity due to obstruction of the outflow tract (ostium or duct) resulting in a cystic lesion of the paranasal sinus, in which the epithelium continuously produces mucus causing expansion of the bony walls of the sinus or air cell cavity.

NOTE: The diagnosis of a paranasal sinus mucocoele is a correlation between clinical, radiographic, and pathologic findings; diagnosis of a paranasal sinus mucocoele by histopathology alone may be extremely difficult given the nonspecific histologic features with the lining of (paranasal sinus) mucocoeles being the same as that of the normal paranasal sinus or the lining associated with nonspecific sinusitis. The expansion of the bony walls of the sinus is a *sine qua non* for paranasal sinus mucocoele.

Clinical

- No gender predilection; may occur in all age groups
- Occur most commonly in the frontal and ethmoid sinuses (>90%):
 - The fronto-nasal duct is relatively long and narrow and thus can relatively easily be obstructed, especially following surgery to this region.

Fig. 2-17. Supraorbital swelling and enophthalmos caused by a large mucocoele.

- The maxillary sinus may be involved but is uncommon (5% to 10%).
- Sphenoid sinus involvement occurs but is considered rare.
- Symptoms depend on the site of involvement as well as the direction and extent of expansion, and include pain, facial swelling or deformity, proptosis, enophthalmos, visual disturbances (e.g., diplopia, loss of vision, sudden blindness), optic neuropathy, rhinorrhea, nasal obstruction:
 - Overall this is a chronic process with signs and symptoms occurring over time rather than an acute process.
- Two types of mucocoeles are identified:
 - **Internal:** herniation of the cyst into submucosal tissue adjacent to the bony wall of the sinus
 - **External:** herniation of the cyst through the bony wall of the sinus with extension into subcutaneous tissue or into the cranial cavity
- Expansion of a mucocoele is in the direction of least resistance.
- Clinical picture may be mistaken for a neoplasm.
- Radiology:
 - Opacification of the involved sinus; with time there is increase in pressure resulting in:

**Fig. 2-18.**

Sagittal T1-weighted MR image (**A**) scan shows an expansile frontal sinus mass with an intermediate signal intensity. This mass had a high T2-weighted signal intensity. This patient had a frontal sinus mucocoele. Sagittal T1-weighted contrast enhanced MR image (**B**) shows uniform mucosal enhancement surrounding the secretions within an expanded frontal sinus. This patient had a frontal sinus mucocoele. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 207, Fig. 3-70.)

**Fig. 2-19.**

Sagittal T1-weighted MR image shows an expansile frontal sinus mass with high signal intensity. The mass has extended down into the medial orbit and back into the anterior cranial fossa. The mass also had a high T2-weighted signal intensity. This patient had a frontal mucocoele. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 208, Fig. 3-71.)

**Fig. 2-20.**

A, Internal mucocoele with herniation of the cyst lined by a respiratory epithelium into submucosal tissue adjacent to the bony wall of the sinus. **B**, External mucocoele with herniation of the cyst lined by a respiratory epithelium through the bony wall of the sinus with extension into the cranial cavity and identification of central nervous system tissue (identified in the majority of the image).

- Erosion and/or destruction of the sinus walls with loss of the typical scalloped outline along the mucoperiosteum
- Abnormal radiolucency due to loss of bone
- Sclerosis of adjacent bone
- The cavity manifests a smoothly contoured expanded wall with reactive bony thickening.
- Based on the strikingly rounded appearance and presence of homogeneous mucoid contents, the radiographic picture can be highly characteristic.
- Irrespective of the sinus involved, the pathogenesis of mucocoeles are thought to occur as a result of an increase in pressure within a given sinus secondary to blockage of the sinus outlet (ostium), most often the result of an inflammatory or allergic process:
 - Additional factors implicated in the development of a mucocoele include trauma, postsurgical or a neoplasm.

Pathology

Gross

- Cysts filled with thick mucoid or gelatinous secretions
- Contents are sterile.
- Cases complicated by infection (pyocoele) are filled with a purulent exudate.

Histology

NOTE: The histologic findings are usually nonspecific, and if one is not aware of this entity and/or the clinical-radiographic findings, then a descriptive diagnosis of essentially normal and/or reactive tissues may be preferred.

- Cysts lined by a flattened pseudostratified ciliated columnar epithelium:
 - In long-standing cases the cyst epithelium may demonstrate squamous metaplasia, but metaplastic changes are uncommon.
- Reactive bone formation can be seen lying in proximity or deep to the epithelial-lined cyst.
- A variable amount of inflammatory cells may be present.
- Additional reactive changes may include fibrosis, granulation tissue, hemorrhage, and cholesterol granuloma formation.

Differential Diagnosis

- Mucous retention cyst

Treatment and Prognosis

- Prognosis is excellent after complete surgical excision:
 - With the introduction of endoscopic sinus surgical instruments and techniques, there has been a

trend toward transnasal endoscopic management of sinus mucocoeles.

- Increasing evidence shows that endoscopic management of sinus mucocoeles results in long-term control with near zero recurrence rates.
- Complications include:
 - Superimposed infection (pyocoele)
 - Meningitis
 - Brain abscess

HETEROTOPIC CENTRAL NERVOUS SYSTEM TISSUE (HCNST) (Figs. 2-21 through 2-24)

Definition: Congenital (often midline) developmental, non-neoplastic displacement of neuroglial tissue in extracranial sites without connection to the cranial cavity.

Synonyms: Nasal glioma; glial heterotopia

NOTE: HCNST is non-neoplastic and therefore the term *glioma* is a misnomer.

Fig. 2-21.

Schematic of the origin of (A) extranasal gliomas and (B) nasal gliomas. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 34, Fig. 1-26.)

Fig. 2-22.

Extranasal heterotopic central nervous system tissue manifesting as a subcutaneous mass along the bridge of the nose.

Clinical

- Occurs in approximately one of 4000 births
- No gender predilection; generally presents at birth or within the first few years of life; however, may affect any age group
- Most commonly occurs in and around the nasal cavity, usually associated with the septum:
 - A midline location with swelling in the nasal bridge area is common.
 - Lesion is usually not strictly midline but may occur more laterally (paramidline), toward or near the inner canthus of the eye.
 - Other sites of involvement include the ethmoid sinus, palate, middle ear, tonsil, and pharyngeal area.
- No evidence of familial predisposition
- Extranasal lesions:
 - Most common, making up approximately 60% of cases
 - Present as a subcutaneous blue or red mass along the bridge of the nose; the skin overlying the swelling or mass may be slightly erythematous.

- Intranasal lesions:
 - Represent approximately 30% of cases
 - Present with obstruction and/or septal deviation
 - Clinically confused with nasal polyps
 - Nasal attachment occurs high within the nasal vault along the lateral wall of the nasal fossa or middle turbinate.
- Mixed extra- and intranasal:
 - Represents approximately 10% of cases
 - Communication occurs through a defect in the nasal bone.
- Negative Furstenberg test (swelling or pulsating lesion following pressure on the ipsilateral jugular vein; typically positive in an encephalocele)
- HCNST most often occurs sporadically but rarely may occur with other congenital abnormalities, including dermal sinus or overlying tuft of hair.
- Radiology:
 - Radiographic studies are indicated to rule out a bony defect that may identify communication to the cranial cavity (encephalocele).
- Prior to biopsy of a lesion in the superior portion of the nasal cavity or base of the nose, detailed clinical and radiographic evaluation of possible continuity with the central nervous system (CNS) is indicated; CNS involvement may be clinically apparent by evidence of meningitis, cerebrospinal fluid rhinorrhea, and anosmia.

Pathology

Gross

- Firm, smooth mass measuring from 1 to 3 cm in diameter appearing gray to yellow and often streaked with white bands
- Rarely described or recognized as brain tissue

Histology

- Composed of astrocytes and neuroglial fibers associated with a fibrous, vascularized connective tissue:
 - Cells in the glial tissue may resemble plump fibroblasts.
- May identify multinucleated or gemistocytic astrocytes
- Neurons are usually absent but may be sparse to few in numbers.
- In long-standing clinically undetected cases, a fibrous stroma may predominate and obscure the astrocytes and neuroglial fibers:
 - In this setting a finely fibrillary glial-type matrix may not be readily apparent.
 - Due to the presence of thick fibrous septa within the lesion and obscuring of neuroglial tissue the entire lesion may be considered as a fibrous proliferation.
 - Fibrous bands tend to circumscribe nodules of the glial tissue resulting in a lobular architecture.

Fig. 2-23. Mixed extranasal-intranasal glioma in a 6-month-old boy.

A, The globular mass overlies the dorsum of the nose on the left. **B**, At surgery the lesion was found to have extended through the left nasal bones, bowed the septum (*S*) rightward, and bowed the residual left nasal bones (*N*) leftward. It was attached by a pedicle to the foramen cecum. **C** and **D**, Coronal and axial CT scans show that the mass extends through the resultant defect into the thickened nasal septum (*white arrowhead* in **D**). The crista galli and brain were normal. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 45, Fig. 1-40.)

- Immunohistochemistry:
 - Astrocytes are immunoreactive with glial fibrillary acidic protein (GFAP) and S-100 protein but are negative for cytokeratins and epithelial membrane antigen.

Differential Diagnosis

- Encephalocele (congenital or acquired):
 - Some consider HCNST to represent a variant of encephalocele in which the communication to the

central nervous system has closed, remains undetected, or has become fibrotic.

- Distinction from an encephalocele is important but may be difficult (see below):
 - The lobular architecture formed by circumscribing fibrous septa is more characteristic of the HCNST.
 - The presence of neurons would be more in favor of an encephalocele, but the absence of neurons does not exclude an encephalocele.

Fig. 2-24. Heterotopic central nervous system tissue.

A, Polypoid-appearing lesion with intact surface squamous epithelium and submucosal cellular proliferation that (**B**) at higher magnification is composed of astrocytes and neuroglial fibers associated with a fibrous and vascularized connective tissue; although not illustrated, the presence of a dense fibrous stroma may obscure the CNS tissue causing the diagnosis of HCNST to be overlooked. **C**, *Left*, irregularly shaped neuroglial cells composed of round to oval nuclei, eosinophilic nucleoli, and abundant granular-appearing cytoplasm; *right*, confirmation of neuroglial origin can be seen by the presence of glial fibrillary acidic protein (GFAP) immunoreactivity.

- In general, encephaloceles are composed of tissue that is more like brain.
- Sinonasal inflammatory polyps
- Teratoma
- Benign peripheral nerve sheath tumor (e.g., neurofibroma)
- Olfactory neuroblastoma
- Presence of gemistocytic astrocytes in the lesion may cause consideration for a malignant lesion.

Treatment and Prognosis

- Surgery is the preferred treatment and results in the cure of the patient:
 - HCNST does not regress and therefore requires management (i.e., surgery).
- 10% recurrence or persistence rate following incomplete excision
- Preoperative assessment for CSF communication is indicated and, if present (i.e., an encephalocele), communication with the CNS necessitates surgical repair.
- Prognosis is excellent.

SINONASAL ENCEPHALOCELE (Figs. 2-25 through 2-27)

Definition: Herniation of brain tissue beyond the confines of the cranial cavity
Synonym: Cephalocele

**Fig. 2-25.**

Schematic of the origin of **(A)** extranasal (glabellar) cephaloceles and **(B)** intranasal transtethmoidal cephaloceles. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 33, Fig. 1-25.)

**Fig. 2-26. Sincipital cephalocele, interfrontal type.**

Three-dimensional CT of the skin surface **(A)** and the bone **(B)** in a 9-year-old girl shows minimal swelling above the glabella with midline cranium bifidum and concavity of the external surface of the frontonasal suture. **C**, Direct coronal CT documents that the sharply margined defect lies superior to the nasofrontal suture, between the two frontal bones. **D**, Sagittal T1-weighted MR image shows fullness at the glabella and herniation of intracranial content through the cranial defect above and external to the nasal bones and nasal capsule. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 48, Fig. 1-42.)

Fig. 2-27. Frontonasal form of frontoethmoidal cephalocele.

A, Three-dimensional CT of the skin surface. The asymmetric glabellar mass obscures the left orbit and projects over the bony and cartilaginous nose. T2-weighted MR images in the axial (**B**) and sagittal (**C**) planes demonstrate hypertelorism, anterior herniation of both frontal lobes into the cephalocele through a defect between the frontal bones and the nasal bones, and asymmetric distension of the sac by CSF. The medial frontal anatomy is distorted by the herniation. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 50, Fig. 1-46.)

Terms:

- Sincipital encephalocele refers to an encephalocele situated in the anterior part of the skull and includes:
 - Interfrontal (cranial defect lies between the two frontal bones)
 - Frontoethmoidal:
 - Nasofrontal
 - Nasoethmoidal
 - Naso-orbital
- Occipital encephaloceles include:
 - Cervico-occipital
 - Low occipital involving the foramen magnum
 - High occipital above the intact rim of the foramen magnum
- Basal encephaloceles may be categorized depending on their point of passage through the skull and the area to where they extend:
- Midline basal encephaloceles include:
 - Transsphenoidal type
 - Sphenoethmoidal type
 - Transethmoidal type
- Lateral basal encephaloceles include:
 - Sphenorbital and sphenomaxillary types

Clinical

- May be classified as congenital (developmental skull defect) or an acquired lesion:
 - Almost all encephaloceles appear to occur sporadically and are not associated with any genetic syndrome(s).
- Prevalence of congenital encephaloceles varies in different parts of the world from about 0.8 to 4 per 10,000 live births.
- More common in Asia than in the western hemisphere
- Ratio of sincipital to occipital lesions varies geographically:
 - Sincipital encephaloceles are about nine times more frequent than occipital ones in Southeast Asia.
 - In Europe and North America the occipital lesions are more common than sincipital ones.
 - Basal encephaloceles are rare (2% to 10% of cases) in all geographic regions.
- Sincipital congenital encephaloceles:
 - Usually form a visible midline or paramidline mass in the region of the bridge (root) of the nose and glabella and are almost always evident at birth
 - Tend to be larger than HCNST
 - Tend to be more compressible than HCNST
 - May be associated with hypertelorism
- Basal encephaloceles:
 - Do not produce a visible facial mass
 - Most involve the midface and may appear as a mass lesion in nasal cavity, nasopharynx, the posterior orbital region, or the sphenomaxillary fossa.
 - May not be evident during infancy and may not present until the patient is significantly older, accounting for a “second peak” of encephalocele incidence around the age of 5 to 10 years
 - Likely the lesions slowly enlarge and thus tend to eventually become more symptomatic.
 - May be clinically mistaken for an inflammatory nasal polyp
- Incidence of acquired sinonasal encephaloceles is unknown:
 - Tend to occur in adults
 - Generally occur as a postsurgical complication
 - May be misdiagnosed as “heterotopias,” and their true nature and genesis goes unrecognized.
 - Some probably related to head trauma other than surgery
 - The cause of some acquired encephaloceles is unclear.
- Radiographic assessment is an important component in the evaluation of these lesions and for detecting evidence of the connection to the central nervous system.

- Embryogenesis:
 - Occipital encephaloceles may be associated with other neural tube closure defects, such as myelomeningocele; associated anomalies may include cleft lip, cleft palate, nasal tip malformation, ocular abnormalities, craniosynostosis.
 - Sincipital encephaloceles are not linked with neural tube defects.
 - Basal encephaloceles may be associated with other anomalies, mostly of the midface, including cleft lip and cleft palate.

Pathology

Gross

- Firm, solid, and tan- to pink-appearing tissue surrounded by a pseudocapsule; small spaces or cystic areas may be identified.

Histology

- Histology is that of normal brain tissue, including neurons; however, due to nutritional impairment of the herniated brain tissue, degenerative and/or reactive changes may be present including gliosis and loss of neurons.
- Vascular congestion or hemorrhage may be present.

Differential Diagnosis

- Heterotopic central nervous system tissue
- CNS neoplasm:
 - Possibility of a neoplasm such as a low-grade astrocytoma may arise.
 - Primary intracranial neoplasm presenting in the sinonasal tract without obvious intracranial origin and extension into the sinonasal tract is highly unlikely.

Treatment and Prognosis

- Treatment for congenital sincipital-basal encephaloceles is surgical (transcranial) resection:
 - In the presence of gross hypertelorism, orbital translocation may be required.
 - Normal development in approximately 60% of cases
- Treatment for acquired encephaloceles is surgery:
 - Repair of a CNS leak may be required.
 - Prevention of meningitis is paramount.
 - Prognosis is very good.

NASAL DERMOID SINUS AND CYST (Figs. 2-28 and 2-29)

Definition: Nasal dermoid cysts are a congenital developmental lesion that are virtually identical to dermoid cysts found in other anatomic locations.

Synonym: Craniofacial dermoids

**Fig. 2-28.**

Diagram of a typical nasal dermal sinus and cyst traversing the prenasal space and the enlarged foramen cecum to form a mass anterior to and within a groove in the anterior concavity of the crista galli. *Inset:* The anatomic relationships of the leaves of the falx to the sides of the crista galli direct upward extension of the mass into the interdural space between the leaves of the falx. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 33, Fig. 1-24.)

Clinical

- Nasal dermoid cysts represent approximately 10% of all dermoids in the cervicofacial region.
- No gender predilection; usually present in infants or young children, but may occur in adults
- Majority are midline swellings at the root of the nose (nasal bridge), although a few may be found in the lower and lateral regions of the nose near the ala:
 - Small lesions or deeply seated cysts may not be apparent until after they become infected and inflamed.
 - Sinus tract with an epidermal opening may be present.
 - Intracranial extension may occur.
 - Rarely, may present with median upper lip fistula
- Radiology:
 - Preoperative evaluation is essential to rule out intracranial extension.
 - Computed tomography (CT) and/or magnetic resonance (MRI) is indicated to delineate deep tissue involvement and to exclude a possible associated intracranial extension.
- Predominance as a midline lesion in the nasal bridge, a similar location as the glial heterotopias, suggests that the development of these two lesions is related.

- May be associated with or coexist with other congenital developmental malformations and may be familial

Pathology

- Cyst with cutaneous appendages (e.g., hair follicles, sebaceous glands, sweat glands) identified in the connective tissue wall
- Lumen is filled with keratin or sebaceous material.
- Respiratory epithelium may be identified.

Differential Diagnosis

- Normal skin surface
- Due to marked alterations secondary to infection, the lesion may be obscured and overlooked.
- Distinction should be made between nasal dermoids and so-called nasopharyngeal dermoids; the latter are not cysts and are actually ectopic accessory auricles.

Treatment and Prognosis

- Curative treatment is surgical:
 - The most important treatment concern is the possibility of the associated existence of a deeply seated cyst or its related sinus tract involving the anterior midline skull base.
 - Radiographic examination to judge the deep extent of the lesion is obviously important in planning operative removal.
- Lesions with intracranial extension have traditionally been managed with lateral rhinotomy, midface degloving, or external rhinoplasty approaches combined with a frontal craniotomy; alternatively, a subcranial approach has been proposed that:
 - Offers excellent exposure
 - Minimizes frontal lobe retraction
 - Reduces the likelihood of cerebrospinal fluid leak
 - Provides for excellent cosmetic result
 - Shows long-term follow-up with no recurrence or negative effect on craniofacial growth
- Low recurrence rates

PRIMARY CILIARY DYSKINESIA (PCD) (Figs. 2-30 and 2-31)

Definition: Primary ciliary dyskinesia (PCD) is a multi-system disease caused by ultrastructural defects of respiratory cilia and sperm tails and characterized by recurrent respiratory tract infections, sinusitis, bronchiectasis, and male subfertility, associated in about 50% patients with situs inversus totalis (Kartagener syndrome).

Synonyms: Immotile cilia syndrome; ciliary dysfunction

Clinical

- PCD is a heterogenetic disorder, usually inherited as an autosomal recessive trait, but pedigrees showing autosomal dominant or X-linked recessive modes of inheritance have been reported.
- Majority of cases are congenital due to an inborn genetic error, but some are acquired, usually the result of epithelial alterations subsequent to inflammatory disease:
 - Acquired forms of the disorder are referred to as secondary ciliary dyskinesia.
- Ciliopathies are a category of diseases caused by disruption of the physiologic functions of cilia:
 - Ciliary dysfunction results in a broad range of phenotypes, including renal, hepatic, and pancreatic cyst formation; situs abnormalities, retinal degeneration, anosmia, cerebellar or other brain anomalies, postaxial polydactyly, bronchiectasis, and infertility.
- Specific clinical features are dictated by the subtype, structure, distribution, and function of affected cilia.
- Presentation for PCD is typically in the early neonatal period:
 - If the diagnosis is considered in older children or in adults and a reasonably reliable clinical history is devoid of evidence of prominent and persistent respiratory tract problems dating from early infancy, the diagnosis is probably not feasible.
- Virtually all patients manifest sinusitis and otitis media, and an associated persistent mucopurulent rhinorrhea is often striking:

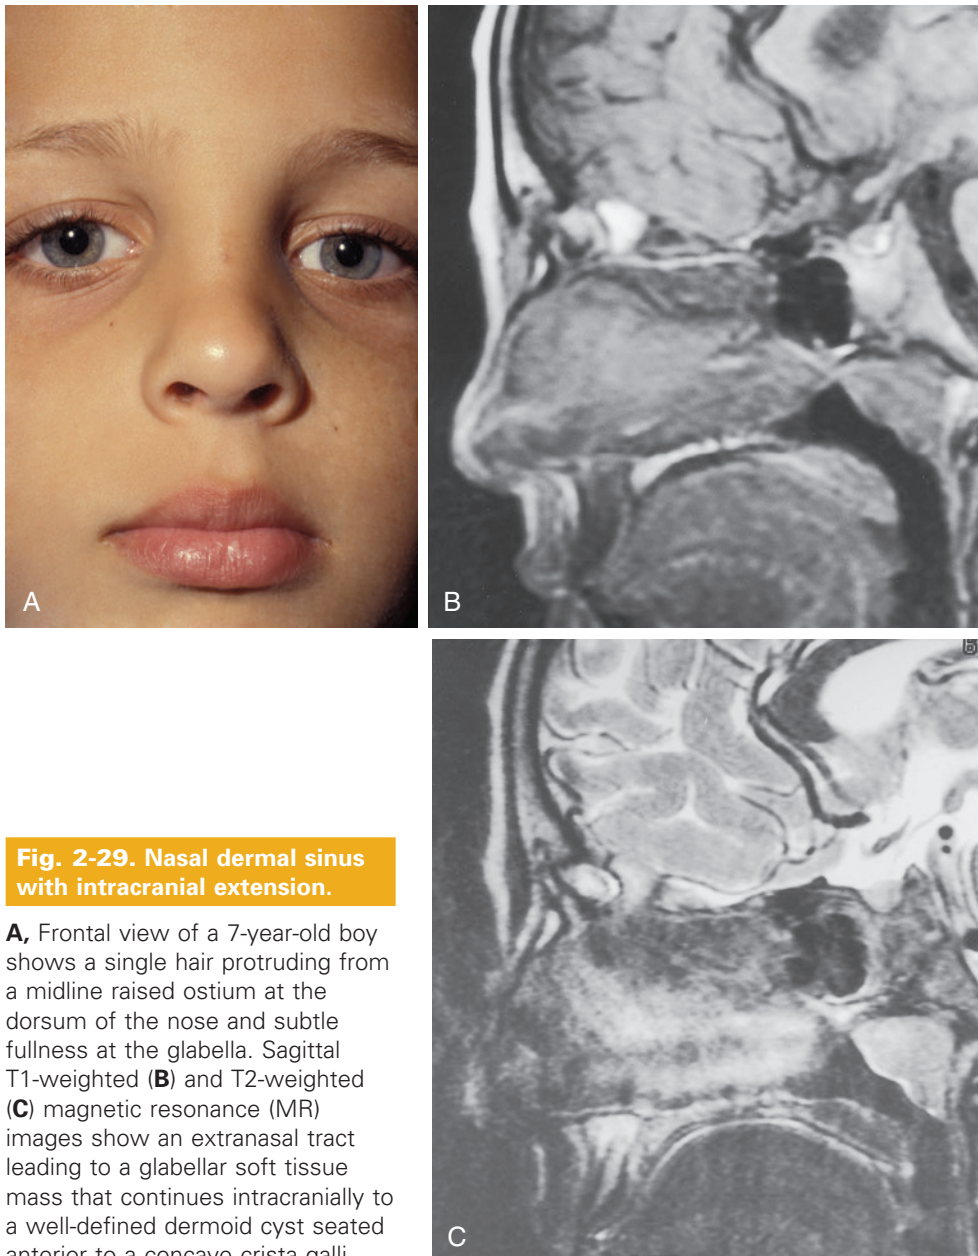

Fig. 2-29. Nasal dermal sinus with intracranial extension.

A, Frontal view of a 7-year-old boy shows a single hair protruding from a midline raised ostium at the dorsum of the nose and subtle fullness at the glabella. Sagittal T1-weighted (**B**) and T2-weighted (**C**) magnetic resonance (MR) images show an extranasal tract leading to a glabellar soft tissue mass that continues intracranially to a well-defined dermoid cyst seated anterior to a concave crista galli.

**Fig. 2-29. cont'd**

D, The probe demonstrates the course of the excised tract in relation to the mass and the dermoid. *Inset*: Close-up of the dermoid that nested in the anterior concavity of the crista galli. **E**, Intraoperative photograph, from above, shows the probe passing from the surgical defect in the nasal bones, through the tract, to the intracranial space anterior to the crista, between the two layers of dura that constitute the falx (see *inset*). (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 38, Fig. 1-34.)

**Fig. 2-30.**

Schematic representation of a cross-section of a ciliary axoneme (main body of the organellum) detailing the normal ciliary structures.

**Fig. 2-31. Primary ciliary dyskinesia.**

Electron microscopic evaluation showed complete absence of dynein arms that confirmed the clinical suspicion for primary ciliary dyskinesia.

- Chronic bronchitis, recurrent pneumonia, and atelectasis are common.
- Presence of situs inversus in association with chronic bronchitis, recurrent pneumonia, and atelectasis is virtually pathognomonic for Kartagener's syndrome, and this clinical scenario generally does not require cilia evaluation for the diagnosis.
- Approximately 50% of patients lack situs inversus, and in this setting ultrastructural examination of cilia is required for diagnostic purposes.
- Exhaled and nasal nitric oxide (NO) measurements have been used to detect PCD in children:
 - Nasal NO is significantly lower in children with proven PCD compared with those with negative biopsy results and healthy control subjects.
 - Nasal NO below a cut-off level of 105 ppb has a reported specificity of 88% for PCD and positive predictive value of 89%.
 - Nasal NO above a cut-off level of 105 ppb excluded PCD with a 100% certainty.
 - Measurement of nasal NO appears to be a useful tool to screen children for PCD and to exclude this disease in those with high nasal NO levels.
- Most patients are currently diagnosed with PCD based on the presence of defective ciliary ultrastructure; however:
 - Diagnosis often remains challenging due to variability in the clinical phenotype and ciliary ultrastructural changes.
 - Some patients with PCD have normal ciliary ultrastructure, further confounding the diagnosis.
 - A genetic test for PCD exists but is of limited value because it investigates only a limited number of mutations in only two genes.
 - Genetics of PCD is complicated owing to the complexity of axonemal structure that is highly conserved through evolution, which is composed of multiple proteins.
 - Identifying a PCD-causing gene is challenging due to locus and allelic heterogeneity.
 - There are a limited number of known PCD-causing genes that combined explain approximately 50% of PCD cases; therefore more genes must be identified.
- For ultrastructural analysis:
 - A nasal cavity biopsy is usually the most easily obtained specimen.
 - Anterior ends of the nasal turbinates are a readily accessible biopsy location, but these areas are where epithelial metaplastic changes are common. In patients with the chronic rhinitis as occurs in PCD, the presence of squamous metaplasia of the anterior turbinate regions is likely and a biopsy from these areas will in all probability contain no cilia. In such a situation, a specimen is best obtained more toward the posterior part of the nasal cavity.
 - If lower respiratory tract endoscopy is done as a part of the patient's evaluation, obtaining a tracheal mucosal brushing or biopsy has a much higher chance of producing a specimen with abundant cilia.
- Gene mutations in PCD:
 - PCD is genetically heterogeneous.
 - PCD-causing mutations have been identified in 20 genes, but collectively they account for only approximately 65% of all PCDs.
 - Ciliary gene mutations are now known to cause single organ disease as well as complex syndromes.
 - Different genes are involved in different patients.
 - Loss-of-function mutations in *ARMC4* cause PCD with situs inversus and cilia immotility, associated with a loss of the distal outer (but not inner) dynein arms.
 - Biochemical analysis in *Chlamydomonas* spp. revealed that the C21orf59 ortholog FBB18 is a flagellar matrix protein that accumulates specifically when cilia motility is impaired:
 - *Chlamydomonas* *ida6* mutant identifies CCDC65/FAP250 as an essential component of the nexin-dynein regulatory complex.
 - Two genes associated with PCD-causing mutations elucidated two distinct mechanisms critical for motile cilia function:
 - Dynein arm assembly for C21orf59
 - Assembly of the nexin-dynein regulatory complex for CCDC65
 - Mutations in SPAG1 cause PCD with ciliary outer dynein arm and inner dynein arm defects.
 - Exome sequencing has identified loss of function mutations in *CCDC114* as a cause of PCD.
 - *ZMYND10* is a cytoplasmic protein required for inner dynein arm and outer dynein arm assembly, and its variants cause ciliary dysmotility and PCD.
 - Loss-of-function *DYX1C1* mutations, a newly identified dynein axonemal assembly factor (DNAAF4) found in patients with PCD
 - *RSPH1* mutations appear as a major cause for this PCD phenotype, including central complex and radial spoke defects.
 - Founder mutation in *RSPH4A* identified as a common cause of PCD without situs abnormalities in patients of Hispanic (Puerto Rican) descent
 - Mutations in *CCDC39* and *CCDC40* are the major cause of primary ciliary dyskinesia with axonemal disorganization and absent inner dynein arms.

- Combining ultrastructural analysis and molecular genetics, the diagnostic yield can be increased:
 - Ciliary biopsy is unreliable as the sole criteria for a definitive diagnosis.
 - Molecular genetic analysis can be used as a complementary test to increase the diagnostic yield.
- In the presence of dynein arms the diagnosis essentially excludes the condition of “absence of dynein arms.”
- The evaluation of dynein arm abnormality is problematic:
 - To make the diagnosis of “absent dynein arms” requires that the sample has multiple ciliary cross-sections that have clear structural detail; otherwise, one cannot be sure that the lack of perception of the arms is not just artifactual.
 - Even in the most technically excellent photographic results one does not see arms on every peripheral tubule doublet because the arms are spaced along the longitudinal axis.
 - If the technical results are mediocre or poor (as most seem to be), it is difficult to clearly see any arms even if the cilia are entirely normal.

Pathology

Electron Microscopy

- The difficulties with interpreting ultrastructural studies of clinical specimens increases the importance and applicability of fresh specimen “wet-prep” examinations of ciliary function as a low-cost effective means of excluding PCD.
- Having abundant cilia in the specimen is critical because it is often difficult to discern dynein arms; the latter is partly due to the fact that:
 - The arms are tiny structures that are focally spaced along the ciliary axonemal tubules and therefore the quantity of electron dense material presented by the tiny arm is meager.
 - The arms are tiny, so relatively high magnification is required.
 - Combined with the meager density of the arm, the need for high magnification results in only a faint image with consequent visual resolution problems.
- Achieving technical results satisfactory for interpretation is a significant challenge.

Normal Cilia

- Internal structure of the axoneme of cilia has classic 9 + 2 microtubular pattern:
 - Pair in center is composed of single microtubules (singlets).
 - Peripheral row of 9 are double-barrelled (doublets) composed of subunits A and B.
 - Two short diverging arms (dynein arms) project clockwise from subunit A of each doublet toward the next doublet.
 - Radial spokes connect subunit A to a central sheath surrounding the central singlets.

Findings in Immotile Cilia Syndrome

- The structural abnormality that is most confidently diagnosable by ultrastructural examination is absence of dynein arms:
 - Dynein arms are necessary for the translational movement of ciliary peripheral doublet tubules with respect to one another (via a biochemico-physical “ratcheting-walking” mechanism); the absence of the arms results in lack of capability for kinetic (i.e., dynamic) movement.

- In the presence of dynein arms the diagnosis essentially excludes the condition of “absence of dynein arms.”
- The evaluation of dynein arm abnormality is problematic:
 - To make the diagnosis of “absent dynein arms” requires that the sample has multiple ciliary cross-sections that have clear structural detail; otherwise, one cannot be sure that the lack of perception of the arms is not just artifactual.
 - Even in the most technically excellent photographic results one does not see arms on every peripheral tubule doublet because the arms are spaced along the longitudinal axis.
 - If the technical results are mediocre or poor (as most seem to be), it is difficult to clearly see any arms even if the cilia are entirely normal.
- The above problems make the diagnosis of “partial absence of arms” or “shortened” or “defective” arms extremely difficult and of suspect validity in most instances; this is especially true of “absent inner arms” because the inner arms usually are seen less well than the outer arms.

Differential Diagnosis

- Diagnosis and differential diagnosis is essentially normal cilia versus abnormal cilia:
 - Avoidance in diagnosing a ciliary abnormality with its implication of an incurable genetic defect should be avoided as an error; such a diagnosis sentences a patient to an unwarranted pessimistic prognosis that could be of major negative emotional impact.
 - If the results strongly suggest a structural defect, it is probably best to obtain another sample from a different anatomic location to see if the same results are obtained.

Treatment and Prognosis

- Presence of ciliary abnormality represents a universal and permanent genetic defect in all of the patient’s cilia and is permanent.
- Early recognition and initiation of otolaryngologic and pulmonary management may reduce potential long-term morbidities.

SINONASAL HAMARTOMAS

- Classification of sinonasal hamartomas is listed in [Box 2-3](#).
- Hamartomas of the sinonasal tract are uncommon:
 - Majority of hamartomas of this region are of the pure epithelial type.
 - Mesenchymal hamartomas or mixed epithelial-mesenchymal hamartomas may occur.

BOX 2-3 Classification of Sinonasal Hamartomas

- Epithelial
 - Respiratory epithelial adenomatoid hamartoma
 - Seromucinous hamartoma
- Mixed epithelial and mesenchymal
 - Chondro-osseous and respiratory epithelial (CORE) hamartoma
- Mesenchymal
 - Nasal chondromesenchymal hamartoma (NCH)

- [Table 2-1](#) details the comparison of various features among sinonasal hamartomas.
- Owing to cases showing histologic features of respiratory epithelial adenomatoid hamartoma and seromucinous hamartoma, these lesions may represent a spectrum of the same lesion instead of different lesions.
- On the basis of the presence of increased fractional allelic loss reported in respiratory epithelial adeno-

TABLE 2-1 Comparison of the Sinonasal Hamartomas

	REAH	SH	CORE	NCH
Age/gender	M > F; third to ninth decades, median sixth decade	M > F; second decade to ninth decade	M = F; second to eighth decades	M > F; most occur in newborns within the first 3 months of life but may occur in the second decade of life, and occasionally in adults
Site(s) of occurrence	Nasal cavity, in particular posterior nasal septum; involvement of other intranasal sites occurs less often and may be identified along the lateral nasal wall, middle meatus, and inferior turbinate; other sites of involvement include the nasopharynx, ethmoid sinus, and frontal sinus	Posterior nasal septum although may occur in the lateral nasal wall, paranasal sinuses, and nasopharynx	Nasal cavity most common; other sites include nasopharynx, ethmoid sinus, and sphenoid sinus	Intranasal mass or facial swelling; may erode into the cranial cavity (through the cribriform plate area)
Histology	Glandular proliferation composed of widely spaced, small to medium glands separated by stromal tissue; glands arise in direct continuity with the surface epithelium, which invaginate downward into the submucosa; glands are round to oval; composed of multilayered ciliated respiratory epithelium often with admixed mucin-secreting (goblet) cells; characteristic finding is the presence of stromal hyalinization with envelopment of glands by a thick, eosinophilic basement membrane; atrophic glands may be lined by a single layer of flattened to cuboidal-appearing epithelium; reactive seromucinous gland proliferation present in between glandular proliferations can be seen	Dense serous gland proliferation with back-to-back appearance resemble a cribriform pattern of growth; glands are lined by low cuboidal to flat epithelium cells with round to oval nuclei and a variable amount of basophilic to eosinophilic to clear appearing cytoplasm; invagination of the surface respiratory epithelium may be seen with at least focal merging with the glandular proliferation; periglandular hyalinization may also be present; lack a significant mucinous cell component, although focal mucinous change may be found; residual seromucinous glands with retention of their lobular architecture and haphazard growth of glands represent important findings that allow for differentiation from sinonasal low-grade adenocarcinoma	Histologic features of REAH (although adenomatoid components tend to be of less prominent) and intimate association with cartilaginous and/or osseous trabeculae	Nodules of cartilage varying in size, shape, and contour; loose spindle cell stroma or abrupt transition to hypocellular fibrous stroma present at the periphery of the cartilaginous nodules; other patterns include a myxoid to spindle cell stroma, fibro-osseous proliferation with cellular stromal component and ossicles or trabeculae of immature (woven) bone; additional findings may include focal osteoclast-like giant cells in the stroma, and erythrocyte-filled spaces resembling those of the aneurysmal bone cyst; mature adipose tissue can be present; proliferating epithelial elements are not a prominent feature

TABLE 2-1 Comparison of the Sinonasal Hamartomas—cont'd

	REAH	SH	CORE	NCH
IHC	Cytokeratin positive (AE1/AE3, CAM 5.2, CK7); negative for CK20 and CDX2; p63 and CK903 (34βE12) staining of basal (myoepithelial) cells but may be absent; S100 may or may not be positive; low proliferation rate	Seromucinous glands reactive for cytokeratins (CK7, CK17, CK19), HMWK; negative for CK14, CK20; p63, calponin, MSA typically negative but in any given case may be positive; S100 protein staining is limited to the seromucinous glands; collagen type IV and laminin staining present around the glandular proliferation; low proliferation rate	None reported	Cartilaginous nodules and mesenchymal stromal component S100 protein staining (more intense staining in cartilaginous components); spindle cell stroma vimentin and smooth muscle actin reactivity; muscle specific actin (HHF35) may be present
Molecular findings	Increased fractional allelic loss (as compared with chronic sinusitis but less than that for adenocarcinoma)	Higher mutation rate in comparison with normal seromucinous glands	None reported	None reported
Associated lesions	Sinonasal inflammatory polyps; hyperplasia and/or squamous metaplasia of the surface epithelium unrelated to the adenomatoid proliferation; osseous metaplasia; rare association with inverted type Schneiderian papilloma, and solitary fibrous tumor; reported instances of low-grade adenocarcinomas associated with REAHs	Sinonasal inflammatory polyps; REAH	None reported	None reported

CORE, Chondro-osseous and respiratory epithelial (CORE) hamartoma; *HMWK*, high molecular weight keratin; *IHC*, immunohistochemistry; *MSA*, muscle specific actin (HHF35); *NCH*, nasal chondromesenchymal hamartoma; *REAH*, respiratory epithelial adenomatoid hamartoma; *SH*, seromucinous hamartoma.

matoid hamartomas, it remains an open issue whether these lesions are non-neoplastic or neoplastic.

- Because our understanding of the nature of these hamartomas is still evolving, this text retains the classification of these lesions as being non-neoplastic and describe respiratory epithelial adenomatoid hamartoma and seromucinous hamartoma as separate lesions, although any given case may show histologic features of both types of hamartomas.

RESPIRATORY EPITHELIAL ADENOMATOID HAMARTOMA (REAH) (Figs. 2-32 and 2-33)

Definition: Benign acquired non-neoplastic overgrowth of indigenous glands of the nasal cavity, paranasal sinuses, and nasopharynx arising from the surface

epithelium and devoid of ectodermal, neuroectodermal, and/or mesodermal elements.

Synonyms: Glandular hamartoma; nasal hamartoma

Clinical

- Predominantly occur in adult patients with a decided male predominance; patients range in age from the third to ninth decades of life with a reported median age in the sixth decade of life.
- Majority occur in the nasal cavity, in particular the posterior nasal septum:
 - Involvement of other intranasal sites occurs less often and may be identified along the lateral nasal wall, middle meatus, and inferior turbinate.
 - Other sites of involvement include the nasopharynx, ethmoid sinus, and frontal sinus.
- Majority of lesions are unilateral but occasionally bilateral lesions may occur.

Fig. 2-32. Respiratory epithelial adenomatoid hamartoma.

Respiratory epithelial adenomatoid hamartoma. **A** and **B**, The histopathologic changes are dominated by the presence of a glandular proliferation composed of widely spaced, small to medium-size glands separated by stromal tissue; in areas the glands can be seen arising in continuity with the surface epithelium invaginating downward into the submucosa; glandular dilatation distended with mucus is present. **C** and **D**, The glands are round to oval, composed of multilayered ciliated respiratory epithelium often with admixed mucin-secreting (goblet) cells; a characteristic feature is the presence of stromal hyalinization with envelopment of glands by a variably thickened, eosinophilic basement membrane. The stroma is edematous or fibrous containing a mixed chronic inflammatory cell infiltrate, and scattered residual seromucinous glands are present.

- Clinical presentation may include one or more of the following symptoms:
 - Nasal obstruction, nasal stuffiness, epistaxis, and chronic (recurrent) rhinosinusitis
 - Symptoms may occur over months to years.
 - Associated complaints include allergies.
 - Nondestructive
- No association with any specific etiologic agent such as environmental or occupational exposure, tobacco use, or alcohol abuse
- Arise in the setting of inflammatory polyps, raising a possible developmental induction secondary to the inflammatory process

Pathology

Gross

- Typically polypoid or exophytic lesions with a rubbery consistency, tan-white to red-brown appearance measuring up to 6 cm in greatest dimension

Histology

- Histopathologic changes are dominated by the presence of a glandular proliferation composed of widely spaced, small to medium-sized glands separated by stromal tissue.

Fig. 2-33. Respiratory epithelial adenomatoid hamartoma.

A and **B**, More prominent stromal hyalinization as compared with Fig. 2-32. This finding is consistent and characteristic of REAH. **C** and **D**, Additional alterations that may be present include the presence of atrophic changes of the surface epithelium and glands, which are lined by a single layer of flattened to cuboidal-appearing epithelium; mucinous metaplasia of glandular epithelium is focally seen and residual seromucinous glands are present.

- In areas the glands are seen arising in direct continuity with the surface epithelium, which invaginate downward into the submucosa.
- Glands are round to oval, composed of multilayered ciliated respiratory epithelium, often with admixed mucin-secreting (goblet) cells.
- Glandular dilatation distended with mucus can be seen.
- A characteristic finding is the presence of stromal hyalinization with envelopment of glands by a thick, eosinophilic basement membrane.
- Atrophic glandular alterations may be present in which glands are lined by a single layer of flattened to cuboidal-appearing epithelium.
- Small reactive-appearing seromucinous glands can be seen; however, some cases may show marked proliferation of seromucinous glands with features of the seromucinous hamartoma (see below).
- Stroma is edematous or fibrous, containing a mixed chronic inflammatory cell infiltrate.
- In addition to the glandular proliferation, additional findings that can be found in association with REAHs include:
 - Histologic alterations of sinonasal inflammatory polyps
 - Hyperplasia and/or squamous metaplasia of the surface epithelium unrelated to the adenomatoid proliferation
 - Osseous metaplasia
 - Rare association with inverted type Schneiderian papilloma, and rare association with a solitary fibrous tumor

- Reported instances of low-grade adenocarcinomas associated with REAHs prompting the consideration that REAHs are a precursor lesion for at least a subset of sinonasal low-grade adenocarcinomas:
 - No definitive proof linking REAH as a precursor lesion to sinonasal adenocarcinoma
- Immunohistochemistry:
 - Glandular proliferation (surface and/or submucosal):
 - Reactive for cytokeratins, including AE1/AE3, CAM 5.2, CK7
 - Negative for CK20 and CDX2
 - p63 and CK903 (34βE12) staining of basal (myoepithelial) cells but in any given case or in areas of any given lesion such staining may be absent:
 - Absence of p63-positive myoepithelial/basal cells does not confer a diagnosis of adenocarcinoma unlike in other organ systems, including the breast and prostate gland, where in conjunction with appropriate light microscopic findings the absence of myoepithelial/basal cells by immunohistochemical staining with p63, smooth muscle actin, and/or smooth muscle myosin heavy chain would support a diagnosis of adenocarcinoma.
 - S100 protein may or may not be reactive.
 - Ki67 (MIB1) staining either is absent or shows a very low proliferation rate (1% to 2%).
 - Molecular genetics:
 - Increased fractional allelic loss (FAL) of 31% falling in between an FAL of 1% for chronic sinusitis and 64% for sinonasal adenocarcinoma:
 - Based on the appreciable allelic loss within hamartomas considered unusually high for a non-neoplastic entity, the possibility that REAHs may be a benign neoplasm rather than a hamartoma has been suggested.
 - Possibility that REAHs are benign neoplasms remains uncertain

Differential Diagnosis

- Sinonasal inflammatory polyp:
 - REAHs may appear polypoid and be mistaken for nasal polyps.
 - Origin of REAHs from the posterior edge of the nasal septum contrasts with the origin of most inflammatory polyps from the lateral portions of the sinonasal tract and rare (if ever) occurrence of inflammatory polyp from the septum.
 - REAHs tend to be firmer than inflammatory polyps; this feature is noted by clinicians who may comment that “this lesion is funny for a inflammatory polyp.”

- Seromucinous hamartoma: see subsequent section
- Schneiderian papillomas
- Nasopharyngeal angiofibroma
- Sinonasal adenocarcinoma, low-grade, nonintestinal, nonsalivary gland type

Treatment and Prognosis

- Conservative, but complete surgical excision is curative.

SEROMUCINOUS HAMARTOMA (SH) (Figs. 2-34 and 2-35)

Definition: Benign acquired non-neoplastic overgrowth of indigenous glands of the sinonasal tract, and rarely of the nasopharynx, arising from submucosally situated seromucinous glands.

Synonym: Glandular hamartoma

Clinical

- Slight male predilection; occurs over a wide age range, including second to ninth decades of life
- Most commonly occurs as an incidental finding seen in surgical material from patients removed for clinical diagnoses such as chronic sinusitis and/or sinonasal inflammatory polyps.
- Symptomatic patients may present with nasal obstruction and epistaxis.
- Most common site of occurrence is the posterior nasal septum, although may occur in the lateral nasal wall, paranasal sinuses, and nasopharynx.
- Generally limited in extent but may extend into adjacent sinuses (e.g., maxillary, ethmoid)
- No known etiologic factors, although some patients have been reported in association with chronic sinusitis, inflammatory polyps, rheumatoid arthritis, and Parkinson disease.
- Radiographically, may appear as polypoid lesion without evidence of aggressive growth such as bone destruction

Pathology

Gross

- Polypoid to exophytic-appearing lesions measuring from 6 mm to 4 cm in greatest dimension

Histology

- Covered by benign ciliated respiratory epithelium that may show squamous metaplasia and often have an associated hypocellular edematous, myxoid, and/or fibrous stroma similar to that seen in sinonasal inflammatory polyps
- Characteristic finding is presence of a submucosal epithelial proliferation of small glands, serous acini

Fig. 2-34. Seromucinous hamartoma.

A, Polypoid to exophytic-appearing lesion with submucosal epithelial proliferation of small glands, serous acini, and tubules growing in clusters and lobules. **B**, In some cases the serous glands may be densely packed with a back-to-back appearance that may resemble a cribriform pattern of growth. **C**, Glands are lined by relatively bland, appearing low cuboidal to flat epithelium cells with round to oval nuclei and a variable amount of basophilic to eosinophilic-appearing cytoplasm. **D**, Residual seromucinous glands with retention of lobular architecture and/or haphazard growth of glands represent important findings that allow for differentiation from sinonasal low-grade adenocarcinoma. **E**, Invagination of the surface respiratory epithelium may be seen with at least focal merging with the glandular proliferation. **F**, Periglandular hyalinization may also be present.

Fig. 2-35. Seromucinous hamartoma.

Immunohistochemical findings. **A**, Most of these lesions are p63 negative. **B**, Some of these lesions are p63 positive. **C**, S100 protein staining is limited to the seromucinous glands. **D**, Collagen type IV is present around the glandular proliferation.

and tubules growing in clusters, and lobules, although haphazard arrangements with larger glands and cysts are seen.

- In some cases the serous glands may be densely packed with a back-to-back appearance that may resemble a cribriform pattern of growth.
- Glands are lined by low cuboidal to flat epithelium cells with round to oval nuclei and a variable amount of basophilic to eosinophilic to clear-appearing cytoplasm.
- There is an absence of significant nuclear pleomorphism, increased mitotic activity, and necrosis.
- Glands vary in appearance from round to oval to angulated to branching and stellate containing luminal mucin material.
- Lack a significant mucinous cell component, although focal mucinous change may be found
- In any given case histologic changes similar to those of respiratory epithelial adenomatoid hamartoma may be present, including:
 - Invagination of the surface respiratory epithelium with at least focal merging with the glandular proliferation
 - Periglandular hyalinization
- Residual seromucinous glands with retention of their lobular architecture and haphazard growth of glands represent important findings that allow for differentiation from sinonasal low-grade adenocarcinoma.
- A mixed chronic inflammatory cell infiltrate composed of mature lymphocytes and plasma cells can be seen, but a significant population of eosinophils is not typically present.

- Immunohistochemistry:
 - Surface epithelium and the seromucinous glands are reactive for cytokeratins, including CK7, CK17, CK19, and high molecular weight cytokeratin (HMWK) but negative for CK14 and CK20.
 - Surface respiratory epithelium show p63-positive basal cells.
 - Myoepithelial/basal cell markers:
 - p63:
 - Seromucinous glands are typically negative but in any given case may be positive.
 - Calponin and muscle-specific actin:
 - Negative in the surface respiratory epithelium and the seromucinous glands but in any given case may be positive
 - Absence of myoepithelial/basal cells by immunohistochemical staining does not confer a diagnosis of adenocarcinoma unlike in other organ systems, including the breast and prostate gland, in which in conjunction with appropriate light microscopic findings the absence of myoepithelial/basal cells by immunohistochemical staining with p63, smooth muscle actin, and/or smooth muscle myosin heavy chain would support a diagnosis of adenocarcinoma.
 - S100 protein staining is limited to the seromucinous glands.
 - Collagen type IV and laminin staining present around the glandular proliferation
 - Ki67 (MIB1) staining is either absent or shows a very low proliferation rate (1% to 2%).
- Molecular genetics:
 - DNA mutation analysis on SH reported to show a higher mutation rate in comparison with normal seromucinous glands, which exhibited a lower mutation frequency (0.83%):
 - Supportive of SH as representing a benign process, although no indications whether such findings support non-neoplastic or neoplastic lesion
 - Suggested similarities between SH and microglandular adenosis of the breast

Differential Diagnosis

- REAH (Table 2-1)
- Schneiderian papillomas
- Sinonasal adenocarcinoma, low-grade, nonintestinal, nonsalivary gland type

Treatment and Prognosis

- Conservative but complete surgical excision is curative.
- No reported recurrences over extended periods of time

CHONDRO-OSSEOUS AND RESPIRATORY EPITHELIAL (CORE) HAMARTOMA (Fig. 2-36)

Definition: Considered to be related to REAHs, but they have the additional feature of chondroid tissue that can be histologically atypical.

Clinical

- Patients range in age from 11 to 73 years.
- Present as polypoid mass most commonly affecting the nasal cavity; other sites of occurrence may include the nasopharynx, ethmoid sinus, and sphenoid sinus.

Pathology

Histology

- In addition to the histologic features of REAH, although the respiratory epithelial adenomatoid components tend to be less prominent, the CORE hamartomas have an intimately associated admixture of cartilaginous and/or osseous trabeculae.
- A spectrum of chondro-osseous differentiation can be found, with some cases manifesting “immature-appearing” mesenchyme, in which cartilaginous plates display a zonal phenomenon resembling endochondral ossification in fetal skeletal development, to cases with well-developed bony trabeculae in a myxoid to fibrous stroma.

Differential Diagnosis

- REAH (Table 2-1)
- Seromucinous hamartoma (see Table 2-1)
- Sarcoma due to the presence of immature-appearing mesenchyme or cartilage

Treatment and Prognosis

- Conservative but complete resection should be curative, although rarely recurrence may occur.

NASAL CHONDROMESENCHYMAL HAMARTOMA (NCH)

(Figs. 2-37 and 2-38)

Definition: Nasal chondromesenchymal hamartoma is a tumefactive process of the sinonasal tract composed of an admixture of chondroid and stromal elements with cystic features that are analogous to chest wall hamartoma. These lesions have some histologic similarities to REAH and CORE hamartoma and they may be within the spectrum of the same type of lesion.

Synonyms: Chondroid hamartoma; nasal hamartoma

Fig. 2-36. Chondro-osseous and respiratory epithelial (CORE) hamartoma.

A and B, Polypoid lesion with intact surface epithelium and a submucosal proliferation of glands (less prominent as compared with the REAHs) and lighter colored areas that represent cartilage. **C,** At higher magnification CORE hamartomas show an admixture of glands and cartilaginous nodules. **D,** A zonal type phenomenon resembling endochondral ossification in fetal skeletal development may be seen.

Clinical

- Rare lesion, with less than 30 cases reported to date
- Male predilection; most of these lesions occur in newborns within the first 3 months of life but may occur in the second decade of life, and occasionally in adults.
- Patients present with respiratory difficulty and an intranasal mass, or facial swelling may be present; some of these tumors have eroded into the cranial cavity (through the cribriform plate area), a finding that may clinically simulate the appearance of a meningoencephalocele.
- Association with pleuropulmonary blastoma reported in a small subset of patients

- Radiology:
 - CT may demonstrate a partially calcified soft-tissue mass obstructing the nasal cavity.

Pathology

Gross

- Firm, polypoid-appearing, tan-yellow mass; cut section may reveal identifiable bone and blue-grey glistening nodules

Histology

- Characterized by the presence of nodules of cartilage varying in size, shape, and contour:
 - Degree of differentiation varies, with some nodules appearing similar to the chondromyxomatous

Fig. 2-37. Chondromesenchymal hamartoma.

A, Low power shows polypoid-appearing sinonasal mucosa with submucosal proliferation of adipose tissue, bony trabeculae, and round (cellular) nodules. **B**, Cartilaginous nodule surrounded by adipose tissue and bone (*upper right*). **C**, Rounded myxochondroid-appearing cellular nodules surrounded by adipose tissue as well as bone and scattered seromucous glands.

- nodules of chondromyxoid fibroma to nodules of well-differentiated cartilage.
 - Chondromesenchymal elements are relatively cellular and “immature,” probably reflecting the immature ages of the patients.
- A loose spindle cell stroma or abrupt transition to hypocellular fibrous stroma is present at the periphery of the cartilaginous nodules.
- Other patterns include a myxoid to spindle cell stroma, fibro-osseous proliferation with cellular stromal component, and ossicles or trabeculae of immature (woven) bone.
- Additional findings may include focal osteoclast-like giant cells in the stroma and erythrocyte-filled spaces resembling those of the aneurysmal bone cyst.
- Mature adipose tissue can be present.
- Proliferating epithelial elements are not a prominent feature.
- Immunohistochemistry:
 - Cartilaginous nodules and mesenchymal stromal component show S100 protein staining:
 - More intense staining in cartilaginous components
 - Spindle cell stroma shows vimentin and smooth muscle actin reactivity; muscle-specific actin (HHF35) may be present:
 - Presence of actin reactivity supports myofibroblastic differentiation.
 - Epithelial membrane antigen (EMA) reactivity has been reported, likely representing nonspecific staining.

Fig. 2-38. Chondromesenchymal hamartoma.

A, Delineated nodular focus of cartilage. **B**, Transitional area between cartilaginous nodule and loosely cellular myxochondroid area. **C**, Cellular myxochondroid area composed of bland spindle-shaped cells.

- Cytogenetics and molecular biology
 - Novel 12;17 translocation, t(12;17)(q24.1;q21) identified as sole reported anomaly
 - Occurred in a single patient (11-year-old boy) with past medical history of pleuropulmonary blastoma

Differential Diagnosis

- REAH, seromucinous hamartoma, and CORE hamartoma (Table 2-1):
 - Nasal chondromesenchymal hamartoma is distinguished from these hamartomas by mostly

presenting in the neonatal age group and by a tendency to be larger and more aggressive than these other hamartomas.

Treatment and Prognosis

- Surgical resection is the treatment of choice that may necessitate combined intranasal and intracranial approach.
- Report of malignant transformation in an adult

INFECTIOUS-RELATED DISEASES OF THE SINONASAL TRACT

FUNGAL DISEASES

(Figs. 2-39 and 2-40)

Aspergillosis

- Sinonasal disease associated with *Aspergillus* sp. is divided into three distinct entities:
 - Allergic fungal sinusitis (AFS)
 - *Aspergillus mycetoma* (“fungus ball”)
 - Invasive fungal sinusitis
- Although most often seen in association with *Aspergillus* species, the above sinonasal fungal diseases may occur with any fungus.

Fig. 2-39.

Axial CT scan (**A**) shows a mass in the left ethmoid and sphenoid sinuses that has broken out into the left orbit. There are discrete areas of high attenuation. The localized areas of high density on this non-contrast-enhanced CT makes an inflammatory process likely. However in **B**, a T2-weighted MR image, the areas of high attenuation in **A** have signal voids. This indicates that they are most likely either desiccated secretions or mycetomas. This patient had aspergillosis. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 203, Fig. 3-60.)

- *Aspergillus* sp. is histologically characterized by relatively thin (2 to 5 μ m) hyphae with acute angle (45 degrees) branching and septation.
- *Aspergillus* is a member of the Moniliaceae family, Hyphomycetes class, Deuteromycota phylum:
 - *Aspergillus* spp. are abundant in soil and in decaying matter.
 - Mode of transmission is via inhalation.

Allergic Fungal Sinusitis (AFS)

Definition: Noninvasive collection(s) of impacted mucus and cellular debris; similar to allergic bronchopulmonary aspergillosis, the pathologic findings result from an allergic response to the presence of a topical fungal colonization within a sinus cavity. The amount of fungal elements is variable and often is quantitatively scanty. Nevertheless, the presence of fungus, irrespective of quantity, elicits an allergic response resulting in a significant pathologic process.

Synonyms: Inspissated mucus; allergic sinonasal aspergillosis; allergic fungal rhinosinusitis; eosinophilic fungal rhinosinusitis; eosinophilic mucin rhinosinusitis; “snotoma”

Clinical

- No gender predilection; may occur in all ages but is most commonly seen in children or young adults
- Tends to be more common in the south and south-west regions of the United States
- Primarily involves the maxillary and ethmoid sinuses but may involve any sinus
- Clinical presentation includes headaches and airway obstruction.
 - Sinus-obstructing inspissates of a characteristic extramucosal “peanut buttery” viscoelastic material
- Patients commonly present with chronic rhinosinusitis with nasal polyps, inhalant atopy, history of asthma, aspirin insensitivity, blood eosinophilia, and elevated total serum immunoglobulin E (IgE) levels.
- Recent studies implicated superantigens and nonimmunoglobulin E (IgE)-mediated mechanisms in the development of AFS:
 - Higher prevalence of *S. aureus* found in patients with AFS versus patients with non-AFS, supporting a potential role for *S. aureus* in the pathogenesis of AFS
- Originally considered solely due to *Aspergillus* species, but other fungi have been found also to be causative, including:
 - Dematiaceous fungi such as *Bipolaris*, *Exserohilum*, *Curvularia*, *Drechslera*, and *Alternaria*

Fig. 2-40. Allergic fungal sinusitis.

A, Inspissated mucus ("allergic mucin") composed of amorphous eosinophilic material associated with nests of inflammatory cells. **B** and **C**, The inflammatory cells predominantly are composed of eosinophils, and Charcot-Leyden crystals can be seen. **D**, The combination of clusters of cohesive cells and homogeneous-appearing chondroid-like matrix may be mistaken for a pleomorphic adenoma; the cohesive cellular nests are inflammatory cells and not epithelial cells. **E**, Rarely, fruiting head of *Aspergillus* sp. may be identified. **F**, (left and right) More typical is the absence of readily identifiable fungal forms that require special stains (GMS) for identification of the fungi that include septated hyphae and acute angle branching.

- Schizophyllum commune, a basidiomycetous fungus, rare cause of AFS confirmed by sequence analysis
- Radiology:
 - Sinus CT is always abnormal, showing findings of chronic rhinosinusitis that often include central areas of increased contrast (“hyperattenuation”).
 - On rare occasions may be associated with bone destruction

Pathology

Gross

- Material removed from the involved sinus is thick, rubbery to firm, translucent to brown or greenish-brown:
 - Secretions may variably be described as greasy, putty-like, peanut butter-like.
 - May be foul smelling
- Material can attain large size, completely filling a sinus, and be quantitatively abundant.

Histology

- Histologic findings are similar irrespective of the fungal organism involved.
- AFS is characterized by the presence of “allergic mucin” composed of amorphous chondroid-like material associated with a prominent inflammatory cell infiltrate:
 - Amorphous material represents inspissated, gelatinized mucus; the material may have a laminated appearance.
 - Inflammatory component is most often composed of eosinophils and neutrophils; scattered plasma cells, lymphocytes, and histiocytes may also be seen.
 - Charcot-Leyden crystals may be seen among the eosinophilic infiltrate:
 - Elongated and needle-like in appearance
 - Composed of lysophospholipase
 - Stain purple-red on trichrome
 - Desquamated respiratory cells can be identified within this amorphous material.
 - Histologic appearance may suggest:
 - Necrotic debris, but on closer inspection necrotic tissue/cells are not identified
 - Epithelial neoplasm such as a pleomorphic adenoma
- Histochemistry:
 - Fungal hyphae may be seen by Gomori methenamine silver (GMS) or periodic acid Schiff (PAS) staining:
 - May be readily identifiable, very limited, or absent
 - Chondroid-like material is mucin positive.

- Fungal forms may be identifiable by special stains, but at times they are scarce; microbiologic culture for speciation is an important diagnostic tool in the identification of a fungal organism.
- Presence of “allergic mucin” is virtually diagnostic for allergic fungal sinusitis, even in the absence of fungal identification by special stains.
- Immunohistochemistry:
 - Epithelial markers (cytokeratins, p63, EMA, others) are negative.
- In situ hybridization (ISH) for abundant fungal rRNA sequences may provide a means for detecting dematiaceous fungi and prove useful for differentiating dematiaceous fungi from other filamentous fungi in fungal rhinosinusitis.

Differential Diagnosis

- Fungus ball (mycetoma) or invasive fungal sinusitis (see below)
- Pleomorphic adenoma
- Misinterpretation of “allergic mucin” as necrotic tissue may suggest the presence of a (necrotic) tumor.
- Rhabdomyosarcoma

Treatment and Prognosis

- Treatment includes surgical debridement and evacuation of involved sinus(es) with postoperative steroid therapy augmented by immunotherapy directed toward the patient’s specific allergen sensitivities:
 - Primary rationale for immunotherapy is to control the allergic diathesis that may be contributing to the patient’s chronic sinus inflammation.
- Antifungal agents are not used unless there is invasion into the tissue; although local topical antifungal agents could be used to reduce antigen load, the efficacy of such measures has not been determined.
- For some patients, recurrences even after clinically adequate initial therapy may occur.
- Approximately 20% of patients may demonstrate paranasal sinus expansion and bone erosion involving surrounding anatomic structures:
 - Such patients may have clinical findings involving the orbit and cranial vault.

Mycetoma (“Fungus Ball”)

(Figs. 2-41 and 2-42)

Definition: Indolent growth of fungal hyphae in a sinus cavity to the point at which a mass is formed.

Clinical

- Symptoms are similar to those of nonspecific chronic sinusitis, except that the symptoms usually are relatively unremitting.

**Fig. 2-41.**

Axial T2-weighted MR image shows inflammatory disease with a high signal intensity in the left maxillary sinus. Centrally within the sinus is a region of low signal intensity and signal void. This was an aspergilloma. This patient had aspergillosis. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 204, Fig. 3-61.)

**Fig. 2-42. Mycetoma (aspergilloma or fungus ball).**

A, The fungal hyphae are so densely packed that they are somewhat distorted and may not be recognized immediately as a mass of hyphae; closer inspection should make it apparent that the material is packed fungal elements. **B**, GMS stain delineates the fungal spores and hyphae.

- Maxillary sinus is by far the most common site of occurrence.
- Radiographs demonstrate sinus opacification:
 - Calcium oxalate deposition commonly accompanies growth of aspergillus, which may be detected radiographically.

- Because the mass of fungal growth is extensive in a fungus ball, this calcium compound may be detected radiographically.

Pathology

- Histologically, the fungal hyphae are so densely packed that they are somewhat distorted and may not be recognized immediately as a mass of hyphae; closer inspection should make it apparent that the material is packed fungal elements.
- Histochemistry:
 - Special stains for fungi (e.g., GMS, PAS) delineate the fungal forms.
- Mucosal-based dense chronic inflammation may be present.
- Tissue invasion by fungi is not present.
- Calcium oxalate crystals appear as radiating clusters of birefringent crystals:
 - Characteristics of *Aspergillus niger* and may be seen in association with *Aspergillus flavus*.
- Differential diagnosis
 - Allergic fungal sinusitis
 - Invasive fungal sinusitis

Treatment and Prognosis

- Conservative treatment, usually consisting of surgical removal of the fungal mass and some increased aeration of the sinus, may be all that is necessary to prevent recurrence of the mycetoma.

Invasive Fungal Sinusitis (Fig. 2-43)

Definition: Acute, fulminant fungal infestation of the sinonasal tract often resulting in destruction of the involved sinus(es) within days.

Clinical

- Typical clinical scenario is the occurrence in immunocompromised patients.
- Presentation includes nasal discharge and sinus pain:
 - Swelling of the face (maxillary area and periorbital region) may be present.
 - With progression of disease, blindness may occur.
- The clinical picture of fulminant infection may be more similar to the clinical picture associated with “mucormycosis” than to the clinical features of the other forms of sinonasal aspergillosis.
- Patients may require immediate surgical debridement, which in turn may necessitate intraoperative consultation (i.e., frozen section) to determine the cause of the fulminant clinical picture:
 - Pathologists are tasked to histologically evaluate for the presence of fungi.
 - In addition to immediate histologic assessment, intraoperative samples should be sent for

Fig. 2-43. Invasive fungal sinusitis.

A, Sinonasal mucosa showing hemorrhage and tissue necrosis with residual identifiable seromucous glands (lower portion of image). **B**, GMS stain shows extensive fungal invasion of sinonasal mucosa within necrotic tissue (upper portion of image); the outlines of viable seromucous glands are present (arrowheads).

microbiologic culture to be sure of the causative fungus.

Pathology

Histology

- Fungal forms are identified throughout resected tissue; when intact, fungi can be seen within mucosal and submucosal tissues, as well as in and around vascular spaces (angioinvasion).
- Tissue necrosis is evident, but an inflammatory response often is limited.
- Histochemistry:
 - Stains for fungi (e.g., GMS, PAS) delineate the fungal forms.

- In situ hybridization (ISH) using specific fungal probes (biotin-labeled oligonucleotide probes targeting *Aspergillus* sp., *Fusarium* sp., *Rhizopus* sp., and a sequence identified in dematiaceous fungi) can effectively identify fungi in (acute) invasive fungal sinusitis as well as in species identification in specimens with negative cultures.

Differential Diagnosis

- Mucormycosis

Treatment and Prognosis

- Treatment requires surgical intervention with anti-fungal chemotherapy:
 - Amphotericin B
 - Triazoles, including itraconazole, posaconazole, and voriconazole
- Increased morbidity and mortality unless prompt therapy is initiated; even with prompt therapy, the prognosis remains guarded:
 - Overall mortality remains high; only half of the patients survive.
 - Patients with diabetes appear to have a better overall survival rate than patients with other comorbidities.
 - Patients who have intracranial involvement or who do not receive surgery as part of their therapy have a poor prognosis.

Sinonasal Mucormycosis

(Figs. 2-44 through 2-46)

Definition: Acute, rapidly evolving fungal infection of the sinonasal region caused by the Zygomycetes class of primitive fungi.

Synonyms: Mucormycosis; zygomycosis; rhinocerebral or rhinorbitocerebral mucormycosis

- Human pathogens in the Zygomycetes class include the orders Mucorales and Entomophthorales.
- Three fungal genera designated *Rhizopus*, *Mucor*, and *Absidia* are included within the order Mucorales, family Mucoraceae.
- These infections are also sometimes labeled after the higher level class grouping of Zygomycetes, formerly Phycomycetes.
- Some species in the order Entomophthorales can cause mild infections, but this is not the severe clinicopathologic entity generally implied by mucormycosis.
- Mucorales sp. appear as relatively large/broad in diameter (10 to 20 μ m), nonseptated hyphae with branching at haphazard angles. Very rare septations may be seen, and the presence of septation does not exclude the diagnosis. Partially distorted hyphae are often seen and frequently appear twisted.

**Fig. 2-44.**

Sinonasal mucormycotic infection in this relatively young immunosuppressed patient resulted in an erosive nasal cavity mass with nasal septal perforation, black necrotic crusts, and gangrenous change.

**Fig. 2-45. Sinonasal mucormycosis.**

In this patient treatment was not immediately initiated and the infectious process spread to facial skin, the eyes, and periorbital tissues, necessitating orbital exenteration.

Clinical

- Mode of transmission is thought to occur via inhalation.
- Patients may present with the signs of an ordinary “cold” with blood-tinged nasal discharge.
- Primarily occurs in adult immunocompromised patients but rarely occur in pediatric immunocompromised patients
- Typical occurrence is in patients with diabetes mellitus, particularly those with the complication of diabetic ketoacidosis and/or immunocompromised patients, including patients with AIDS:

**Fig. 2-46. Sinonasal mucormycosis.**

A, At low magnification the appearance is that of an “ischemic type” geographic necrosis with effacement of the normal mucosal architecture, although residual seromucous glands are focally present; the ischemic type necrosis is due to the angiotropism of the fungi with thrombosis of the involved vessel(s) and subsequent tissue necrosis. **B**, *Left panel*, although there is minimal inflammation the tissue is infested by (*right panel*) innumerable fungi that in contrast to *Aspergillus* sp. are relatively large/broad in diameter and have nonseptated hyphae with branching at haphazard angles.

- Due to immunosuppression or diabetic acidosis, body defenses are not sufficient to ward off the invading organism.
- Black necrotic crusts appear on the nasal mucosa.
- Nasal septal perforation may ensue.
- Gangrenous change may develop rapidly and, unless aggressive therapeutic intervention ensues, the process may spread to facial skin, the eyes and periorbital tissues, and into the central nervous system; spread to distal anatomic sites may occur.
- *Rhizopus* sp. is the most commonly cultured species of the three genera that cause sinonasal mucormycosis.

- Radiology:
 - Extension of disease from the nasal cavity and paranasal sinus may include orbital involvement resulting in extension of the inflammatory process along the infraorbital fissure into the infratemporal fossa and extension into the cavernous sinus.
 - Clinically, orbital involvement may include proptosis, ptosis, ophthalmoplegia, loss of vision, and orbital cellulitis.

Pathology

Gross

- Tissue fragments often are hemorrhagic and dark in appearance owing to tissue necrosis.
- Given the need for aggressive surgical debridement, the tissue fragments may include bone.

Histology

- Diagnostic finding is the presence of fungal hyphae within resected tissues; the fungi are usually identifiable by hematoxylin and eosin staining (see above for description of the fungal forms).
- Fungi are angiotropic, including perivascular localization and angioinvasion; the latter includes through the vessel wall and into the lumen:
 - Luminal involvement may result in complete obstruction and thrombosis that may result in tissue necrosis (“gritty” type necrosis) in a geographic pattern; similar findings can be seen in aspergillosis, granulomatosis with polyangiitis (formerly Wegener granulomatosis), and nasal type NK/T cell lymphoma.
- Surrounding tissues include a mixed inflammatory cell infiltrate, hemorrhage, and necrosis; rarely, foreign body–type multinucleated giant cells may be identified, within which fungi may be identified.
- Histochemistry:
 - Stains for fungi (e.g., GMS, PAS) delineate the fungal forms.

Differential Diagnosis

- *Aspergillus* sp. or an aspergillus-like fungus:
 - In comparison to *Mucor* sp., *Aspergillus* and aspergillus-like fungi are generally smaller, more uniform in size, more uniformly show acute angle branching of the hyphae, and show the presence of septations.
- Granulomatosis with polyangiitis (formerly Wegener granulomatosis)

Treatment and Prognosis

- Therapy includes surgical removal of necrotic or gangrenous tissue and administration of amphotericin B.

- Increased morbidity and mortality unless prompt therapy is initiated; even with prompt therapy, the prognosis remains guarded:
 - Overall mortality remains high, with only half of the patients surviving.
 - Patients with diabetes appear to have a better overall survival than patients with other comorbidities.
 - Patients who have intracranial involvement or who do not receive surgery as part of their therapy have a poor prognosis.

Rhinosporidiosis (Figs. 2-47 and 2-48)

Definition: Chronic infectious disease of the upper respiratory tract (nasal cavity and nasopharynx) characterized by formation of polypoid masses and caused by the sporulating organism *Rhinosporidium seeberi* (*R. seeberi*).

Clinical

- Endemic in India, Sri Lanka, and Brazil with only sporadic occurrence in the United States
- More common in men than in women; affects all ages but most common in the third and fourth decades of life
- Thought to be a zoonotic organism, as rhinosporidiosis seen in cattle, horses, and mules
- Mode of transmission is thought to occur via water or dust from which the endospore penetrates the

Fig. 2-47. Rhinosporidiosis.

The resected specimen is a polypoid mass that grossly resembles sinonasal inflammatory polyps.

Fig. 2-48. Rhinosporidiosis.

A, Sinonasal rhinosporidiosis appearing as a polypoid lesion characterized by the presence of multiple submucosal cysts (sporangia); the overlying epithelium is hyperplastic with associated squamous metaplasia. **B**, Submucosa with multiple, variably sized sporangia. **C**, The sporangia contain innumerable endospores; an associated chronic inflammatory response consisting of lymphocytes, plasma cells, and eosinophils accompany the microorganisms; cysts may rupture, resulting in a microabscess formation (not shown), but usually a granulomatous reaction is not present. **D**, Although the microorganisms (*R. seeberi*) are readily identifiable by hematoxylin and eosin staining, additional stains may be used to detail these fungi, including, *left*, periodic acid-Schiff (PAS), and *right*, mucicarmine.

nasal cavity mucosa, matures into sporangium within the submucosal compartment, and following maturation the sporangia burst with release of endospores into surrounding tissue.

- Most common sites of involvement are the nasal cavity (inferior turbinate along the lateral nasal wall) and the nasopharynx:
 - Infection may involve the mucosa of the larynx, tracheobronchial tree, esophagus, pharyngeal-oral, palpebral conjunctiva, and ears.
- Most common symptoms include nasal obstruction, epistaxis, and rhinorrhea.
- Infection is a chronic, indolent one, and the causative organism does not seem to be contagious; patients are usually healthy.
- *R. seeberi* is a fungal organism that does not grow on synthetic media (although it has been propagated in cell culture media).

Pathology

Gross

- Single or multiple polypoid, pedunculated, or sessile masses:
 - Grossly resemble sinonasal inflammatory polyps
- Cut section shows pink to purplish-appearing tissue with glistening mucoid surface; microcysts may be seen in the submucosal stroma.

Histology

- Mucosal and submucosal cysts (sporangia) ranging in size from 10 to 300 μ m in diameter
- Sporangia contain innumerable sporangiospores (endospores) seen by hematoxylin and eosin; two sizes of sporangiospores may be seen, including:
 - Smaller spores measuring approximately 1 to 2 μ m in diameter

- Larger spores measuring approximately 5 to 10 μm in diameter
- Larger spores are the more mature forms.
- Larger spores tend to congregate toward the center with the smaller being more peripheral, creating a zonated appearance relative to spore size.
- Smaller cystic structures (without sporangiospores) ranging from 10 to 100 μm are also seen:
 - These smaller cystic structures are called trophocysts.
 - Considered to result from autoinfection via mature sporangiospores released from ruptured sporangia
 - Sporangia and trophocysts have eosinophilic walls measuring several μm in thickness.
- A chronic inflammatory response consisting of lymphocytes, plasma cells, and eosinophils accompanies the microorganisms.
- Rupture of the cysts induces an acute inflammatory response; however, a granulomatous reaction is not seen.
- Overlying epithelium may be hyperplastic and/or demonstrate squamous metaplasia.
- Histochemistry:
 - Microorganisms stain with periodic acid-Schiff (PAS) and mucicarmine.

Differential Diagnosis

- Coccidioidomycosis infection (*Coccidioides immitis*):
 - *R. seeberi* is usually much larger than *C. immitis*.
 - The wall of *R. seeberi* stains with mucin.
 - *C. immitis* does not stain with mucin.
- Schneiderian papilloma, cylindrical cell type:
 - Surface epithelial neoplastic proliferation that occasionally can be confused with rhinosporidiosis:
 - Histologically characterized by epithelial neoplastic proliferation (see next chapter)
 - Intraepithelial cysts are seen in Schneiderian papilloma, cylindrical cell type, whereas the cysts associated with rhinosporidiosis are intraepithelial and submucosal.

Treatment and Prognosis

- Surgical excision
- Recurrences, necessitating additional surgical excision, may occur in up to 10% of cases.
- No antibiotic therapy is effective.

Other Fungi (Fig. 2-49)

- Other fungal diseases of the sinonasal tract include sporotrichosis, blastomycosis, coccidioidomycosis, cryptococcosis, and histoplasmosis.
- Sinonasal infection by these fungal diseases is rare.

- *Sporotrichum schenckii* is the causative organisms in sporotrichosis and may be the cause of a primary nasal cavity infection.
- Sinonasal blastomycosis, coccidioidomycosis, cryptococcosis, and histoplasmosis rarely infect the sinonasal tract; infection of other sites (especially the lungs) often is part of the clinical picture.
- Infection with these fungi may result in pseudoepitheliomatous hyperplasia that clinically and pathologically may suggest an epithelial neoplasm.

BACTERIAL INFECTIONS

Rhinoscleroma (Fig. 2-50)

Definition: Chronic granulomatous infectious disease primarily occurring in the upper respiratory tract (nasal cavity and nasopharynx) caused by *Klebsiella rhinoscleromatis*.

- *K. rhinoscleromatis* is a gram-negative diplobacillus of the family Enterobacteriaceae:
 - Organism measures about 2.5 μm in length and is encapsulated.
 - Can be cultured on simple media
 - Not considered contagious (or is only minimally so)

Synonyms: Scrofulous lupus; scleroma; organism also referred to as “Frisch bacillus,” named for Anton von Frisch who identified organism in 1882

Clinical

- No gender predilection; can occur in all ages but tends to be more common in young age groups, including the first three decades of life
- Disease of lower socioeconomic class in which poor living conditions and malnutrition fosters the growth and spread of disease
- Endemic in Egypt, parts of Central and South America, North and Central Africa, and Eastern Europe
- Occurs but considered uncommon in the United States
- Infection manifests initially in the nasal cavity (nasal septum) and spreads posteriorly to the nasopharynx; other sites of involvement include the paranasal sinuses, orbit, larynx, tracheobronchial tree, and middle ear.
- Three clinical phases/stages, including:
 1. Rhinitic, exudative, or catarrhal stage:
 - Characterized by mucopurulent nasal discharge
 - This stage can continue for many months or even years; appearance of a granular nasal mucosa can herald the progression to the next stage.

Fig. 2-49. Sinonasal blastomycosis.

A, The induction of a pseudoepitheliomatous hyperplasia in the face of blastomycotic infection may suggest an epithelial neoplasm; intraepithelial microabscesses including giant cells and giant cells within the submucosa are present.

B, Numerous multinucleated giant cells are present within the submucosa. **C**, *Left panel*, intraepithelial giant cells contain (*right panel*) fungi (GMS stain). **D**, *Left panel*, submucosal giant cells contain (*right panel*) fungi (GMS stain).

E, Under oil immersion the microorganism is encapsulated and located within a giant cell.

Fig. 2-50. Sinonasal rhinoscleroma.

A, A diffuse submucosal infiltrate is present, replacing seromucous glands with squamous metaplasia of the overlying epithelium; although not depicted here, rhinoscleroma may be associated with pseudoepitheliomatous hyperplasia. **B**, The cellular infiltrate in rhinoscleroma includes an admixture of mature lymphocytes, plasma cells, scattered eosinophils, and neutrophils, but the predominant cell type is macrophages with clear to foamy cytoplasm (Mikulicz cells). **C**, Warthin-Starry silver stain demonstrates the presence of the *K. rhinoscleromatis*, a gram-negative bacteria, within the macrophages.

2. Florid or proliferative stage:
 - Marked by mucosal thickening, which may result in nasal obstruction; diagnosis is usually made in this phase.
 - Results in a mass-like growth composed of firm nodules (consistency of cartilage) and a reddish appearance
 - Mass lesion may cause nasal expansion and deformity with some facial mutilation.
 - Bone erosion may contribute to radiographic findings, raising suspicion for a malignancy.
3. Fibrotic or cicatricial stage:
 - Represents resolution of disease
 - Generally follows therapy initiated during the second stage
 - Results in “burnt-out” fibrosis causing deformity but nasal discharge abates (relatively dry nose) and without further progression locally
 - Spread to other areas of the respiratory tract may occur during this phase.

- Reported in association with extranodal sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman disease)

Pathology

Gross

- Typically, in the florid or proliferative phase the infected mucosa is pale in appearance and demonstrates diffuse nodular thickening.

Histology

- Characteristic lesion seen in the florid or proliferative phase consists of a submucosal granulomatous infiltrate composed of macrophages with clear to foamy cytoplasm (Mikulicz cells) intimately associated with an admixture of lymphocytes and numerous plasma cells:
 - Macrophages (Mikulicz cells) harbor the bacteria
 - Number of Mikulicz cells varies with the stage of the disease; in the proliferative stage they are plentiful and readily identifiable.

- Overlying epithelium may demonstrate a squamous metaplasia or pseudoepitheliomatous hyperplasia; rarely, ulceration is seen.
- Characteristic Mikulicz cells may be difficult to identify in the fibrotic phase.
- Histochemistry:
 - Organisms (bacterial rods) are best detected by silver stain (Warthin-Starry stain).
 - Tissue Gram stain and Giemsa stain may also reveal the microorganisms but may be falsely negative.
- Immunohistochemistry:
 - Macrophages (Mikulicz cells) are CD68 positive but negative for S100 protein, CD1a, and Langerin.
- Primarily occurs as a skin-related lesion; rarely affects viscera (e.g., lung, liver, kidney, bowel, brain, orbit, spleen, lymph nodes, tonsil, sinonasal tract)
- Localized lesion that may clinically simulate the appearance of an aggressive neoplasm:
 - May occur in healthy individuals, patients with chronic disease or immune compromised conditions (e.g., cystic fibrosis, diabetes mellitus, chronic granulomatous disease, AIDS, other)
 - Patients with sinonasal disease may present with persistent headache, bulging eye.
 - Radiographic evidence of an expansile paranasal sinus-based lesion with bony erosion may be present.
- Histopathology includes:
 - Presence of amorphous, acellular material with deposition of proteinaceous material and inorganic compounds
 - Separate, rounded eosinophilic grains or granules associated with a neutrophilic infiltrate:
 - Grains or granules contain the causative bacterial organisms.
 - Club-like or radiating projections form along the periphery and are referred to as the Splendore-Hoepli phenomenon:
 - Considered to represent an antigen-antibody reaction
 - Can be seen in association with other organisms including actinomyces, fungi, bacteria, helminthes, mycetoma, phycomycosis, as well as in association with silk sutures
 - Filamentous gram-negative bacilli morphologically compatible with *P. aeruginosa* identified, but bacteria may not be readily identifiable, and if this diagnosis is not considered and/or if the pathologist is not familiar with this entity, the diagnosis may be overlooked.
 - Histochemical bacterial stains (Gram, Brown and Hopps) delineate the presence of bacteria.

Differential Diagnosis

- Syphilis
- Extranodal sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman disease)
- Inflammatory (pseudo)tumor/plasma cell granuloma
- Clinically, may be suggestive of granulomatosis with polyangiitis (formerly Wegener granulomatosis) or a malignant lymphoma

Treatment and Prognosis

- Treatment of choice is long-term antibiotic therapy (tetracycline, streptomycin, thiopenicol, ciprofloxacin) followed by surgical debridement.
- Surgical resection may be necessary where airway obstruction may be life threatening.
- CO₂ laser surgery may represent an alternative means of therapy.
- Prognosis is good following initiation of antibiotic therapy, although may be high recurrence rates:
 - High rates of recurrence necessitate long-term follow-up.

Miscellaneous Sinonasal Bacterial Infections

Pseudomonas aeruginosa (Botryomycosis) (Fig. 2-51)

- Botryomycosis is a chronic bacterial infection analogous to a “fungus ball,” except the mass of microorganisms is composed of bacteria, usually *Pseudomonas* sp., that usually is a cutaneous (skin and subcutaneous tissue) lesion and uncommonly is mucosal based.
- Term *botryomycosis* is used to describe a lesion resembling mulberry or a “bunch of grapes” (Greek *botryos*), which was initially believed to be caused by a true fungus.
- **Synonym:** Also referred to as “bacterial ball”

- Microbiologic cultures confirm *Pseudomonas* infection.
- Surgical evacuation is curative.
- Botryomycotic lesions are generally resistant to antimicrobial therapy:
 - Due to associated fibrosis and the compactness of the granules characteristic of botryomycotic lesions, therapeutic drug levels may not reach the microorganisms.

Mycobacteria leprae (Fig. 2-52)

- Leprosy, also referred to as Hansen disease, is an infection caused by *Mycobacterium lepra*.
- Leprosy is characterized by cutaneous, mucosal, and peripheral nerve involvement.
- The microorganism:

Fig. 2-51. Sinonasal botryomycosis (bacterial ball).

A, T1-weighted, gadolinium-enhanced axial MRI showing left sinus opacification with mass-like extension into the ethmoid sinus and nasal cavity. **B**, Amorphous, acellular material with deposition of proteinaceous material and inorganic compounds. **C**, At higher magnification separate, rounded eosinophilic grains or granules associated with a neutrophilic infiltrate are seen; the grains or granules contain the causative bacterial organisms. **D**, Filamentous gram-negative bacilli morphologically compatible with *P. aeruginosa* are present (Gram stain). **E**, Splendore-Hoeppli phenomenon characterized by the presence of club-like or radiating projections forming along the periphery can be seen in botryomycosis but is not unique to this lesion and can be seen in association with other organisms, including actinomyces, fungi, bacteria, helminthes, mycetoma, phycomyces, as well as in association with silk sutures.

Fig. 2-52. Sinonasal leprosy (Hansen disease), lepromatous leprosy.

A, Diffuse submucosal inflammatory cell proliferation; due to decrease in the host's cell-mediated immunity there is no granulomatous inflammation as would be expected in tuberculoid leprosy. **B,** At higher magnification numerous vacuolated histiocytes (so-called lepra cells) are present. **C,** Abundant *M. lepra* microorganisms are present within the vacuolated histiocytes (lepra cells) by special stain (Fite [modified acid-fast bacilli] stain).

- Has low infectivity and exposure rarely results in infection
- Is believed to require cool host body temperature for survival
- Affects cooler peripheral areas of the body including digits, ears, nose, nasal cavity
- Sinonasal tract (mucosal) involvement is fairly common in patients with this infection and may be important in the transmission of the disease:
 - Nasal secretions contain high numbers of infectious bacilli.
 - Initial site of infection may be the nasal or oropharyngeal mucosa.
 - Oral lesions are not uncommon.
 - Less common sites of involvement of the upper aerodigestive tract include the larynx.
- Patients with sinonasal tract involvement may present with mucopurulent rhinosinusitis, nose-bleeds, and anosmia:
 - Early lesions may appear plaque-like.
 - Late lesions may be ulcerative and nodular and may result in collapse of the bridge of the nose.
- Due to involvement of peripheral nerves, pain and muscular atrophy, as well as sensory loss, frequently occur:
 - Sensory loss begins in the extremities and spreads to the rest of the body.
- Host genetic factors are thought to influence susceptibility to infection as well as disease progression:
 - Variants of genes in the NOD2-mediated signaling pathway (which regulates the innate immune response) are associated with susceptibility to infection with *M. leprae*.
- Two main clinical presentations occur based on the immune reaction to the microorganism:
 - Tuberculoid leprosy (TL):
 - Also referred to as paucicellular leprosy
 - Develops in patients with high immune reaction

- Disease is usually localized.
- Lepromin skin test is positive:
 - Purified suspension of heat-killed microorganisms
- Microorganisms are typically absent in skin biopsy.
- Lepromatous leprosy (LL):
 - Also referred to as multibacillary leprosy
 - Develops in patients with reduced cell-mediated immune reaction
 - Disease is usually diffuse.
 - Face is a common site of involvement and may result in so-called leonine facies due to skin enlargements and facial distortion.
 - Lepromin skin test is negative.
 - Microorganisms are typically present in skin biopsy.
- Variants include borderline tuberculoid and borderline lepromatous.
- Histology:
 - Tuberculoid leprosy characterized by:
 - Well-formed granulomatous inflammation with admixture of histiocytes, multinucleated giant cells, and lymphocytes
 - Paucity of microorganisms by special stains
 - Lepromatous leprosy characterized by:
 - Absence of granulomatous inflammation
 - Presence of sheets of lymphocytes and vacuolated histiocytes (lepra cells)
 - Abundant microorganisms by special stains
- For both types the histopathologic process is typically submucosal.
- Involvement of nerves by the inflammatory reaction is a helpful diagnostic finding.
- Histochemistry:
 - Special stains for microorganisms including acid-fast bacilli, Fite stain assist in identifying the presence of organisms.
- *M. leprae* does not grow on artificial media.
- Rapid quantitative serologic test assists in the detection of *M. leprae* infection:
 - Early detection of infection followed by effective treatment is critical to reduce disease progression.
 - New leprosy serologic test (NDO-LID) detects larger proportions of leprosy infection than alternative standard diagnostics leprosy test, including detection of paucibacillary leprosy.
 - Quantifiable nature of this NDO-LID also can be used to monitor treatment efficacy.
 - NDO-LID assists in diagnosis and monitoring of leprosy and can detect a significant number of earlier-stage infections.
- Molecular biologic techniques (polymerase chain reaction) assist in detecting the presence of microorganisms.

- Treatment includes:
 - Antibiotic therapy:
 - Rifampin and dapsone for tuberculoid leprosy (6-month course)
 - Rifampin and dapsone and clofazimine for lepromatous leprosy (12-month course)
 - Reconstructive surgery

Other Mycobacterial Infections

- *M. tuberculosis*:
 - Uncommon in sinonasal tract
 - Characterized by presence of well-formed caseating granulomatous inflammation
 - Acid-fast bacilli may be seen by special stains (i.e., AFB) but may be scarce to absent.
 - Microbiologic cultures may be helpful, although mycobacteriae are slow-growers and may take weeks.
 - Molecular biologic techniques facilitate the identification of the microorganism.
 - Differential diagnosis primarily with sarcoidosis
 - Well-formed granulomas are not a feature associated with granulomatosis and polyangiitis (formerly Wegener granulomatosis); rather, scattered multinucleated giant cells are present.
 - See Section 4, Neck, for discussion of *M. tuberculosis*.
- Other mycobacterial infections rarely present in the sinonasal tract including atypical mycobacterial infection:
 - May occur in immunocompromised individuals (e.g., AIDS)
 - In immunocompromised patients, the inflammatory response may not include a granulomatous inflammatory reaction; rather, a mixed inflammatory reaction including lymphocytes and histiocytes may be present.
 - Unless there is a high index of suspicion, this diagnosis may be overlooked.
 - Special stains for acid-fast bacilli confirm the presence of microorganisms.

Syphilis

- For a more complete discussion see Section 2, Oral Cavity.
- Syphilis is a systemic venereal disease caused by *Treponema pallidum*, a member of the family Spirochaetaceae that includes *T. pertenue* (yaws) and *T. carateum* (pinta).
- Clinical stages of syphilis are primary, secondary, tertiary, and congenital, any of which can affect virtually every site in the head and neck.
- Protean clinical manifestations include involvement of the head and neck, including:
 - Tonsillar involvement
 - Skin lesions and lymphadenopathy

- Pharyngotonsillitis
- Other head and neck symptoms in the secondary stage include rhinitis, laryngitis, pharyngitis, cranial nerve deficits, sensorineural deafness, labyrinthitis, and glossitis.
- Tertiary stage typically involves the central nervous system (neurosyphilis) and aorta (cardiovascular syphilis); however, localized, non-progressive lesions may develop in mucosal otolaryngic sites termed “benign tertiary syphilis” or “gummas”; the gummatous reaction represents a pronounced immunologic reaction of the host.
- In patients with a clinical “midline destructive” condition in the nasal cavity, the differential diagnosis may include tertiary syphilis.
- Histology includes a plasma cell endarteritis:
 - Nasal mucosal plasmacellular inflammation conceivably could represent secondary syphilis.
 - Diagnosis may be overlooked if not considered.
 - Serologic testing for syphilis may prove valuable.
 - Nontreponemal (nonspecific) antibody tests
 - Treponemal (specific) antibody tests
 - These tests are most reactive in the secondary stage of disease.

PROTOZOAL NASAL INFECTIONS

Mucocutaneous Leishmaniasis (Fig. 2-53)

- Leishmaniasis is a protozoal infection caused by different species of *Leishmania*; the parasite is transmitted by the bite of an infected female phlebotomine sandfly.
- The disease is prevalent throughout the world.
- Three forms of disease:
 - Cutaneous (Oriental or tropical sore):
 - Caused by *Leishmania tropica* (in Asia and Africa) and *Leishmania mexicana* (in Central and South America)
 - Endemic in the Middle East, around the eastern Mediterranean, in North Africa, and in parts of Asia
 - Acute lesions are usually single papules that may become nodules, ulcerate, heal, and leave a scar.
 - Chronic lesions (persist for 1 to 2 years) are single or occasionally multiple, raised non-ulcerated plaques.
 - Recidivous (lupoid) form includes erythematous papules, often circinate near scars of previously healed lesions

Fig. 2-53.

Mucocutaneous leishmaniasis caused by *Leishmania braziliensis* may result in (A) ulcerative and (B) destructive lesions of the sinonasal tract; this is referred to as espundia. C, The organisms of *L. braziliensis*, referred to as amastigotes, are found within histiocytes often localizing along the periphery of the cells (so-called marquee sign); the organisms are small, ovoid to round with a thin cell membrane, large nucleus, and lack a capsule, which is a differentiating feature from *Histoplasma capsulatum*.

- Disseminated form (primary diffuse cutaneous leishmaniasis) develops in anergic individuals as widespread nodules and macules without ulceration or visceral involvement:
 - Some authorities consider diffuse cutaneous leishmaniasis to represent a fourth form of disease.
- Tardive form represents the development of a lesion at the site of recent cutaneous surgery with the likely source of infection occurring over 5 decades previously.
- Mucocutaneous:
 - Caused by *Leishmania braziliensis*
 - Endemic to Central and South America, or in travelers to those areas
 - Initial lesions resemble those of the cutaneous form
 - Disseminated anergic form is rare and may occur in immunocompromised individuals (e.g., AIDS).
 - Development of destructive ulcerative lesions of mucous membranes referred to as espundia
 - Upper aerodigestive tract sites of involvement include the sinonasal tract, nasopharynx, oral cavity (tongue).
- Visceral:
 - Acute or chronic infection caused by *Leishmania donovani*
 - Synonyms include Kala-azar, dumdum fever, and black fever
 - Widely distributed but occurs predominantly in South America, Africa, the Mediterranean basin (Italy, Greece), and Asia
 - Infects multiple organs and may result in fever, hepatosplenomegaly, weight loss, anemia, and thrombocytopenia
- Leishmaniasis usually starts as a cutaneous lesion at any of a number of sites.
- Sinonasal mucocutaneous infection represents secondary spread from cutaneous infection.
- Histology of mucocutaneous infection includes:
 - Ulceration with marked lymphoplasmacytic cell infiltrate and granulation tissue
 - Pseudoepitheliomatous hyperplasia of the surface epithelium may be present.
 - In the immune competent patient, the inflammatory response may be vaguely granulomatous with some epithelioid histiocytes and scattered giant cells, as well as necrosis (necrotizing granuloma):
 - Number of microorganisms present may be sparse.
 - In diffuse anergic leishmaniasis there is absent granulomatous inflammation and presence of numerous large histiocytes with associated lymphocytes and plasma cells:
 - Numerous microorganisms are present.
- Microorganisms referred to as amastigotes are:
 - Found within histiocytes; tend to be localized at the periphery of the macrophages (so-called marquee sign)
 - Small, ovoid to round and measure 1.5 to 3 μ in diameter
 - Have a thin cell membrane, large nucleus, and a rod-shaped kinetoplast
 - Seen by hematoxylin and eosin staining
 - Nucleus and kinetoplast accentuated by Giemsa stain
 - Often require oil immersion for identification
 - Absence of a capsule assists in differentiating *Leishmania* from *Histoplasma capsulatum*
- Clinical history, especially travel to endemic area, may be necessary to suspect the possibility of this infection.
- Molecular biologic techniques (polymerase chain reaction) assist in detecting the presence of microorganisms.
- Treatment:
 - Various drugs, including antifungal ketoconazole, reported to be effective
 - The most promising drug found is an anticancer compound, miltefosine:
 - Belongs to the alkylphosphocholine group
 - Found to be 94% to 97% effective
 - Limitations include:
 - Cannot be given during pregnancy
 - Shows severe gastrointestinal side effects
 - Very costly
 - Other drugs such as paromomycin, allopurinol, and sitamaquine have been reported with variable cure rates.
 - Combination therapy is recommended, preferably coupled with specific parasite enzyme inhibitors.

VIRAL INFECTIONS

- See Section 2, Oral Cavity, for a more complete discussion on viral diseases.
- Viral infestation of the sinonasal tract is uncommon, but mucocutaneous disease with herpes simplex virus (HSV) and cytomegalovirus (CMV) may occur, especially in immunocompromised patients.
- Human papillomavirus (HPV) and Epstein-Barr virus (EBV) may be seen in association with specific sinonasal tract neoplasms:
 - HPV and Schneiderian papillomas
 - EBV and nasal type NK/T cell lymphoma
 - HPV and carcinomas:
 - See next chapter for HPV-associated sinonasal neoplasms.

SARCOIDOSIS

- See Section 4, Neck, for a complete discussion on sarcoidosis.
- Sarcoidosis of the sinonasal tract may be subclinical and not cause prominent symptoms; occasionally, sinonasal tract involvement may result in a mass-like lesion, and bone erosion may be present.
- Histology is typical for sarcoidosis, including well-formed, non-necrotizing (noncaseating) granulomas; granulomas may be small and scattered in the submucosa.
- A nasal mucosal biopsy in a patient thought clinically to have sarcoidosis may help provide support for the diagnosis.

MYOSPHERULOSIS (Fig. 2-54)

Definition: Innocuous iatrogenically induced pseudomycotic disease resulting from the interaction of red blood cells and petrolatum-based ointments.

Nomenclature: Myospherulosis was initially described in Africa, where lesions affected primarily subcutaneous tissues or muscle, resulting in the designation “myo”-spherulosis.

Clinical

- Typically, prior to the development of a nasal cavity or paranasal sinus mass patients had prior surgery for a variety of disease processes (inflammatory or neoplastic lesions) followed by packing of the area with a petrolatum-based or paraffin-based tetracycline/steroid (Terra-Cortril) ointment:
 - Similar lesions have been seen following surgery involving the ear.
 - Similar lesions reported in soft tissue areas of the extremities.
- Lesion is a chronic, fibrotic tissue reaction resulting from injected or applied medicament that acts as a foreign substance:
 - Origin of the myospherules is from red blood cells, which react with petrolatum or lanolin.

Fig. 2-54. Myospherulosis of the sinonasal tract.

A, Dense fibroconnective tissue within which are embedded multiple, irregularly shaped cystic spaces. **B,** Myospherulosis pseudocystic spaces contain round, saclike structures (“parent bodies”). **C,** The “parent bodies” are brown staining and contain numerous spherules or endobodies; stains for microorganisms are absent.

- Found in ointment used in “packing” the nasal cavity after surgery
- Emulsified fat may also induce the formation of myospherules so that fat necrosis may result in myospherulosis.
- In the nose and paranasal sinuses symptoms generally relate to a mass lesion with or without airway obstruction; local pain and tenderness, signs of malaise, and fever can occur:
 - Lesions may develop from a month to a couple of years after a sinonasal tract surgical procedure.
- Preoperative diagnosis can be suggested on CT of the paranasal sinuses by presence of macroscopic paraffin retention cysts with characteristic fat density.

Pathology

Gross

- No specific macroscopic findings other than a non-descript mass

Histology

- Pseudocysts or microcysts are embedded within fibrotic tissue, creating a “swiss-cheese” appearance.
- Pseudocysts or microcysts:
 - Measure up to 1 mm in diameter
 - Are irregular in contour
 - Contain round, saclike structures called “parent bodies”:
 - Parent bodies measure approximately 50 μ m in diameter.
 - “Parent bodies” in turn contain numerous spherules or endobodies.
 - Spherules or endobodies:
 - Measure approximately 5 μ m in diameter
 - Are variable in size and shape, with cup-shaped forms being common
 - Are usually dark brown in color
- Chronic inflammatory infiltrate composed of lymphocytes, histiocytes, giant cells, and plasma cells:
 - Inflammatory cell infiltrate can be sparse.
 - Occasional multinucleated giant cell of foreign body type may be seen.
- Histochemistry:
 - Stains for microorganisms are negative.
- Characteristic spherules may be sparse or absent; the diagnosis can be suggested even in the absence of spherules given appropriate history, anatomic location, and presence of fibrotic tissue with empty spaces.

Differential Diagnosis

- Fungal infections (rhinosporidiosis, coccidioidomycosis)

Treatment and Prognosis

- Symptomatic treatment that may include conservative surgical removal of fibrotic tissues, which is effective mode of treatment
- Prevention by the use of non-petrolatum-based antibiotic substances

SINUS HISTIOCYTOSIS WITH MASSIVE LYMPHADENOPATHY (ESHML) (Fig. 2-55)

Definition: Idiopathic histiocytic proliferative disorder generally characterized by lymph node–based disease and an indolent behavior; extranodal manifestations occur, with the upper respiratory tract being among the more common sites of involvement.

Synonyms: Rosai-Dorfman disease; Destombes-Rosai-Dorfman syndrome

- Often a nodal-based proliferation occurring as part of a generalized process involving lymph nodes
- May involve extranodal sites independent of the lymph node status
- Head and neck region represents one of the more common extranodal areas affected:
 - Within the head and neck, there is predilection for the nasal cavity and paranasal sinuses.
 - Virtually all head and neck sites may be affected in association with or independent of nodal disease.

Clinical

- Slightly more common in women than in men; occurs over a wide age range
- May be identified in virtually all extranodal head and neck sites, including:
 - Sinonasal cavity > orbit/eyelid > salivary gland > oral cavity (palate) > lower respiratory tract > nasopharynx and tonsil > middle ear and temporal bone > larynx > trachea
- Symptoms depend on the site of occurrence:
 - In the sinonasal tract symptoms predominantly relate to nasal obstruction.
 - Nonsinonasal tract–related symptoms include proptosis, ptosis, decreased visual acuity, pain, stridor, cranial nerve deficits, or a mass lesion.
- Presentation often includes multiple concurrent sites of involvement; may occur without evidence of lymph node involvement.
- In general, the diagnosis of ESHML is a pathologic diagnosis rarely, if ever, suspected by clinical evaluation.

Fig. 2-55. Sinonasal tract extranodal sinus histiocytosis with massive lymphadenopathy (ESHML).

A, Submucosal diffuse inflammatory cell infiltrate with effacement of the normal submucosal structures; a benign lymphoid aggregate is present to the right of center that in conjunction with the cellular infiltrate has an architectural appearance reminiscent to that of lymph node parenchyma. **B**, Lymphoid aggregate is present at the left and is associated with a mixed cellular infiltrate composed of histiocytes admixed with lymphocytes, plasma cells, and scattered eosinophils. **C**, At higher magnification the infiltrate includes mature lymphocytes and plasma cells that somewhat obscure the histiocytic cell infiltrate; the latter demonstrates phagocytization of mononuclear cells (emperipolesis). **D**, Clusters of histiocytes predominate in this field and are composed of round nuclei with abundant clear to lightly eosinophilic cytoplasm within which an occasional mononuclear cell can be seen (emperipolesis). **E**, The histiocytes are diffusely immunoreactive for S-100 protein (but are CD1a and Langerin negative, not shown). **F**, The inflammatory cell infiltrate may extend into adjacent tissue structures, including bone.

- Hematologic and immunologic status generally intact but may be associated with polyclonal elevations in serum protein levels and raised erythrocyte sedimentation rates
- SHML has occurred in association with HIV-infected patients, Sjögren syndrome, and amyloidosis and may coexist with Langerhan cell histiocytosis.
- Although some studies implicated SHML to be an IgG4-related disease, it is not believed to belong within spectrum of IgG4-related diseases.
- Discrepancy in the literature relative to relationship to Epstein-Barr virus (EBV) and human herpes virus (HHV):
 - Some studies report elevated levels of EBV, as well as HHV6 in association with SHML.
 - Other studies report SHML cells are not infected by EBV or associated with HHV6 and HHV8.
- Cause for SHML remains obscure:
 - An infectious cause has been suggested as the cause, but an infectious agent has never been isolated.
 - Occurrence in patients with rhinoscleroma suggests a possible causative relationship with rhinoscleroma, although this has not been proven.
 - Other considerations implicated but never substantiated include immunodeficiency, autoimmune disease, or a neoplastic process.
- Immunophenotypic studies support the interpretation that the SHML cells are part of the mononuclear phagocyte and immunoregulatory effector (M-PIRE) system belonging to the macrophage/histiocytic family:
 - Stimulation of monocytes/macrophages via macrophage colony stimulating factor (M-CSF) leading to immune suppressive macrophages represents a main mechanism for the pathogenesis of SHML and provides evidence for the monocyte/macrophage but not dendritic cell differentiation of SHML histiocytes.
 - Expression of the chemokine receptors CCR6 and CCR7 in the SHML histiocytes suggests that this may be a general attribute of abnormal histiocytes and may reflect gene activation in a more mature macrophage-derived cell type.

Pathology

Cytology

- Cytologic features suggesting the diagnosis include numerous large benign histiocytes with emperipolesis.

Gross

- Mucosal thickening or polypoid, nodular, or exophytic growths with rubbery to firm consistency, pink to tan-gray color, and variation in the size

Histology

- At low magnification, the histopathologic features include the presence of fibrosis and lymphoid aggregates alternating with pale-appearing areas composed of histiocytes, lymphocytes, and plasma cells within the submucosa.
- Fibrosis may be focal or may appear as prominent fibrotic bands creating a nodular appearance to the gland.
- Lymphoid aggregates are composed of mature lymphocytes and may contain histiocytic cells imparting a mottled appearance to these aggregates; true germinal centers are not usually seen.
- In addition to the lymphoid aggregates, a polymorphous cellular infiltrate composed of mature lymphocytes, plasma cells, and histiocytes is seen:
 - Histiocytes (so-called SHML cells) appear in clusters or cell nests but may be obscured by the nonhistiocytic cell population (particularly the plasma cells).
 - Histiocytic cells are uniform with mild pleomorphism and are characterized by round to oval, vesicular to hyperchromatic nuclei, with an abundant amphophilic to eosinophilic, granular to foamy to clear cytoplasm.
 - Nuclei do not demonstrate nuclear lobation, indentation, or longitudinal grooving.
 - Histiocytes characteristically demonstrate emperipolesis; the phagocytized cells usually are lymphocytes, but plasma cells, erythrocytes, and polymorphonuclear leukocytes can also be seen engulfed within the histiocytic cell cytoplasm; emperipolesis may be less common as compared with nodal-based SHML.
 - Lymphocytes and plasma cells are nondescript.
 - Intracytoplasmic eosinophilic globules (Russell bodies) can be seen within the plasma cells.
 - Neither granulomas (well formed or otherwise) nor multinucleated giant cells are identified.
- Histochemistry:
 - Special stains for infectious organisms are negative but are required for differential diagnosis.
- Immunohistochemistry:
 - SHML cells are diffusely S100 protein positive but negative for CD1a and Langerin.
 - SHML cells may also demonstrate alpha-1-antichymotrypsin (ACT), CD68 (KP1), lysozyme, and MAC-387 immunoreactivity.
 - Plasma cells demonstrate a polyclonal pattern of proliferation as seen by the cytoplasmic positivity for both kappa and lambda light chains.
 - A subset of SHML cases reported to have features of IgG4-related disease suggest an overlap between certain aspects of the two diseases.

Differential Diagnosis

- Infectious (granulomatous) diseases:
 - Rhinoscleroma
 - May include the presence of emperipolesis
- Leprosy
- Langerhan cell histiocytosis:
 - Langerhan cells are immunoreactive for S100 protein, CD1a, and Langerin.
- Fibroinflammatory lesions
- Granulomatosis with polyangiitis (formerly Wegener granulomatosis)
- Hematolymphoid malignancy:
 - Heterogeneous cell population typical for SHML as well as the presence of emperipolesis, CD68 and S100 protein reactivity should allow for differentiation from a hematolymphoid malignancy.
 - Although rare, emperipolesis can be seen in association with B-cell lymphomas.
 - SHML on rare occasions has been identified in lymph nodes affected by malignant lymphomas, including non-Hodgkin lymphomas, multiple myeloma, and Hodgkin disease, mixed cellularity type.
 - Transformation of SHML to a high-grade lymphoma has also been reported.

Treatment and Prognosis

- Considered an indolent, self-limiting disease; severe morbidity and mortality have been attributed to complications of SHML.
- There is no ideal treatment for involvement of the head and neck.
- Treatment protocols should mirror the clinical manifestations such that a range of therapeutic modalities may be used:
 - In cases of airway compromise, treatment should be directed at alleviating the obstruction, which would require surgical intervention.
 - For those patients with extensive or progressive disease, more radical surgical intervention may be required.
 - Surgical eradication of disease may prove difficult in cases with craniofacial bones and/or cranial cavity involvement.
 - Radiotherapy and chemotherapy have been used, but the efficacy of these agents has not been proven.
 - Patients with progressive disease course and/or compromise of vital structures and functions may be treated with combination chemotherapy including etoposide or 6-mercaptopurine plus low dose methotrexate potentially with favorable outcomes.
- Extension of disease to vital structures, particularly to the cranial cavity, may result in the death of the patient; however, mortality related to SHML is a rare occurrence.

- Unfavorable prognostic factors include disseminated nodal disease, involvement of multiple extranodal organ systems, and deficiencies in hematologic and/or immunologic status.

GRANULOMATOSIS WITH POLYANGIITIS (GPA)

(Figs. 2-56 through 2-59)

Definition: GPA is a non-neoplastic, idiopathic aseptic necrotizing disease with predilection for the upper/lower respiratory tract and the genitourinary system characterized by the presence of vasculitis and destructive properties.

This classic definition calls for involvement of the head and neck region, the lung, and the kidney. The majority of GPA patients do not exhibit this classic clinical triad simultaneously at the time of initial presentation. Therefore it is possible that, in a given patient, the initial biopsy material may originate from lesions of the upper aerodigestive tract (UADT) in the absence of a clinical suspicion for GPA.

Synonym: Wegener granulomatosis

Clinical

- GPA may be systemic or localized; the extent of disease is reflected in the clinical manifestations such that limited or localized disease may be asymptomatic, whereas in systemic involvement the patient is always sick.
- Disease may progress from localized to systemic involvement or may remain limited or even regress with treatment.
- ELK classification of GPA includes: E = ear, nose, and throat involvement; L = lung involvement; K = kidney involvement:
 - Patients with E or EL disease are considered to have the limited form of GPA.
 - Patients with ELK disease correspond to systemic GPA.
 - The incidence of limited GPA varies from 29% to 58%.

Localized Upper Aerodigestive Tract (UADT) GPA

- Localized UADT GPA tends to affect men more than women except in laryngeal GPA, which is seen predominantly in women.
- GPA occurs over a wide age range with the average age of occurrence in the fourth and fifth decades of life.
- In the UADT, the most common site of occurrence is the sinonasal region with the nasal cavity > maxillary > ethmoid > frontal > sphenoid.
 - Other sites of involvement include nasopharynx, larynx (subglottis), oral cavity, ear (external and

Fig. 2-56. Granulomatosis and polyangiitis.

Severe nasal deformity is seen including nasal septal destruction.

Fig. 2-57. Granulomatosis and polyangiitis.

The lesion began in the nasal cavity with erosion through the floor of the nasal cavity resulting in complete erosion through the palate.

- middle ear including the mastoid), and salivary glands.
- Symptoms vary according to the site of involvement and include:
 - Sinonasal tract and nasopharynx: sinusitis with or without a purulent rhinorrhea, obstruction, pain, epistaxis, anosmia, headaches

- Larynx: dyspnea, hoarseness, voice changes:
 - Involvement of the larynx is seen more often in the setting of pre-existing disease elsewhere, and so presentation with laryngeal GPA is a rare event.
 - Between an estimated 8% and 25% of patients with GPA will develop disease referable to the larynx.
 - Laryngeal involvement most often involves the subglottic region.
- Oral: ulcerative lesion, gingivitis
- Ear: hearing loss, pain
- Radiographic features of sinonasal GPA include:
 - Sinus opacification, bone destruction, ossification of the sinus walls, and soft tissue destruction
- Laboratory studies:
 - Useful laboratory studies include elevated erythrocyte sedimentation rate and, in renal disease, elevated serum creatinine and abnormal urinary sediment.
 - An important laboratory finding in GPA is an elevated antineutrophil cytoplasmic antibody (ANCA):
 - Reported specificity for the diagnosis of GPA from 85% to 98% of cases
 - ANCA reactivity is seen in the form of cytoplasmic (c-ANCA) versus perinuclear (p-ANCA) staining.

Fig. 2-58. Granulomatosis and polyangiitis.

A and B, At low magnification the changes include the presence of multifocal necrobiosis (“geographic or ischemic-type” necrosis) with a basophilic smudgy appearance; scattered areas of inflammation and thrombotic-like changes of vascular spaces are present. **C,** Vasculitis, a potentially difficult finding on histology, is seen here with the inflammatory infiltrate concentrically surrounding a blood vessel (angiocentric) and invading through the wall (angioinvasion) with occlusive changes of the endothelial lined lumen. **D,** Elastic stain, which may be of assistance in identifying vasculitis, shows the disruption of the black-staining external elastic membrane by the angiocentric and angioinvasive inflammatory cell infiltrate. The latter in both **C** and **D** is a mixed (benign) infiltrate including variable numbers of mature lymphocytes, plasma cells, and eosinophils.

- GPA is characteristically associated with cytoplasmic (c-ANCA) and only infrequently with perinuclear (p-ANCA).
- c-ANCA is of greater specificity than p-ANCA.
- Sensitivity of the test varies with the extent of disease:
 - Patients with limited GPA have a 50% to 67% c-ANCA positivity.
 - Patients with systemic GPA have a 60% to 100% positivity.
 - Negative test does not rule out GPA.
- Elevated in other vasculitides and in inflammatory bowel disease and hepatobiliary diseases
- ANCA titers are not elevated in infections or in lymphomas.
- ANCA titers follow the disease course; titers will revert to normal levels with remission and

will be elevated with recurrent or persistent disease.

- Decline in C-ANCA titer may lag behind clinical evidence of remission by up to 6 to 8 weeks.
- Proteinase 3 (PR-3):
 - PR-3 is a neutral serine proteinase present in azurophil granules of human polymorphonuclear leukocytes and monocyte lysosomal granules.
 - PR-3 serves as the major target antigen of anti-neutrophil cytoplasmic antibodies with a cytoplasmic staining pattern (c-ANCA) in GPA.
 - ANCA with specificity for PR3 are characteristic for patients with GPA.
 - Patients with GPA demonstrate a significantly higher percentage of mPR3+ neutrophils than

Fig. 2-59. Granulomatosis and polyangiitis.

A through **D**, The inflammatory cellular components are polymorphous, composed of variable admixture of mature lymphocytes, plasma cells, histiocytes, eosinophils, and neutrophils without evidence of atypical or overtly malignant cells. In all the illustrations are isolated multinucleated giant cells that represent the granulomatous component of the disease ("poor man's" granuloma), because well-formed granulomas are not typically identified in granulomatosis and polyangiitis despite its designation as a granulomatous process. **E**, Neutrophilic microabscess formation is another feature that can be seen whether associated with necrobiosis (*left of center*) or unrelated to necrosis (not shown). **F**, The inflammation extends into and through elastic cartilage, a contributing component to the clinical findings of saddle nose deformity and/or septal destruction. Finding vasculitis, necrosis, and granulomatous inflammation in a single case occurs in less than 20% of cases, and detailed clinical correlation including serum ANCA and PR3 levels is often required to support the histopathologic findings to confirm the diagnosis of granulomatosis and polyangiitis.

healthy controls and patients with other inflammatory diseases.

- Detection of ANCA directed against proteinase 3 (PR3-ANCA) is highly specific for GPA.
- ANCA positivity is found only in about 50% of the patients with localized GPA, whereas PR3-ANCA positivity is seen in 95% of the patients with generalized GPA.
- Pathogenesis of vascular injury in GPA is ascribed to antineutrophil cytoplasmic antibodies directed mainly against PR-3.
- Interaction of ANCA with neutrophilic ANCA antigens is necessary for the development of ANCA-associated diseases; ANCA bind to membrane-expressed PR-3 and induce full-blown activation in primed neutrophils.
- In patients with GPA, high expression of PR3 on the surface of nonprimed neutrophils is associated with an increased incidence and rate of relapse.
- ANCA-associated vasculitis (AAV) includes GPA, microscopic polyangiitis (MPA), allergic granulomatous angiitis (AGA), and eosinophilic GPA (Churg-Strauss disease):
 - Major target antigens of AAV are PR3 and myeloperoxidase (MPO).
 - PR3-ANCA is the marker for GPA.
 - MPO-ANCA is related to MPA and AGA.
 - ANCA appears to induce vasculitis by directly activating neutrophils.
 - No immunoglobulins or complement components are detected in vasculitis lesions; as such, AAV is called pauci-immune vasculitis.
 - ANCA directed against proteinase 3 (PR3) preferentially associated with GPA
 - Anti-myeloperoxidase (MPO) ANCA are associated mainly with MPA and eosinophilic GPA.
- Genome-wide analysis of patients with ANCA-associated vasculitides confirmed genetic contribution to the pathogenesis of these conditions:
 - Significant association of PR3-ANCA and human leukocyte antigen-DP and the genes encoding α 1-antitrypsin and PR3
 - MPO-ANCA were significantly associated with human leukocyte antigen-DQ.
- Despite decades of intensive investigation, the cause of GPA remains unknown:
 - Although speculative, an infectious cause (e.g., bacterial) either as the cause or as a co-factor in the disease is suggested on the basis of:
 - Reported beneficial effects of trimethoprim-sulfamethoxazole therapy on the initial course of the disease
 - Histologic features of the disease are similar to what might be found in infectious diseases.

Pathology

Gross

- Sinonasal area: diffuse ulcerative and crusted lesions with tissue destruction; in advanced cases, septal perforation may be seen resulting in a “saddle nose” deformity.
- Laryngeal area: subglottic stenosis with associated ulcerative lesions
- Oral cavity: ulcerative, destructive lesions often seen along the palate and alveolar region

Histology

- Histologic features of GPA include the classic triad of: (1) vasculitis, (2) granulomatous inflammation (which may involve vessel walls as well as the supporting tissues), and (3) tissue necrosis:
 - In practice, however, it has become apparent that finding all of three of these “characteristic” features in a single or even a series of biopsies is actually very uncommon.
 - Accordingly, the pathologist faces the twin risks of underdiagnosing GPA when all of the classic histologic components are lacking and of overdiagnosing GPA when excessive reliance is placed upon the presence of minimal histologic changes that fall far short of the classic findings expected.
 - Presence of all three defining criteria in the same head and neck region biopsy is decidedly unusual, seen in only 16% of biopsies from patients with proven GPA.
 - As a consequence, the diagnostic pathologist must be prepared to advance the *possibility* of GPA (among other differential diagnostic considerations) even when the full-blown range of classic histologic changes is not present in the biopsy.
 - Clearly, requiring the presence of all classic features of GPA in a single biopsy before the possibility of GPA is advanced results in “nondiagnostic” interpretations being rendered for the majority of head and neck biopsies from patients with the disease.
- Vasculitis involving small to medium-sized arteries consists of a polymorphous inflammatory infiltrate composed of lymphocytes and histiocytes and less often eosinophils and polymorphonuclear leukocytes:
 - Vasculitis may be difficult to identify histologically and is often absent.
 - Inflammatory infiltrate is angiocentric (surrounding vessels) and angioinvasive (invading through the vessel wall) and may result in thrombosis of the involved blood vessel.

- Vasculitis is not limited to GPA and can be seen in infectious diseases (e.g., mucormycosis, aspergillosis) as well as in NK/T cell lymphoma.
- Necrosis is “ischemic” or “geographic”-type (multifocal necrobiosis) with a basophilic smudgy appearance:
 - Necrotic foci should be within the stromal connective tissues and not along the surface or edge of the tissue specimen, which may represent nonspecific ulceration seen in a wide variety of lesions.
- Granulomatous inflammations are not well-formed granulomas but include the presence of scattered isolated or less common clustered multinucleated giant cells:
 - Well-formed granulomas uncommonly occur and when present should raise concern for an infectious cause.
- Parenchymal inflammatory infiltrate is composed of predominantly lymphocytes, histiocytes, and plasma cells; eosinophils, although generally uncommon, may be numerous on occasion.
- Microabscesses with or without granuloma formation may be identified.
- Bacterial superinfection of the diseased mucosa, particularly *Staphylococcus aureus*, may complicate the clinical picture.
- Histochemistry:
 - Elastic stains may assist in the identification of vasculitis.
 - Because GPA is a diagnosis of exclusion, staining for microorganisms should be performed but is invariably negative.
- Immunohistochemistry:
 - Immunoreactivity for both B-cell (CD20) and T-cell (CD3) markers indicative of a benign (polyclonal) cellular population
 - Immunohistochemical staining for EBV and/or in situ hybridization for Epstein Barr encoded RNA (EBER) is negative.
- IgG4 immunostaining:
 - Increased IgG4+ cells can be seen in sinonasal (or orbital/periorbital) biopsies of GPA.
 - This finding could pose a pitfall in the diagnosis of IgG4-related disease.
 - GPA in other organs and controls does not show increased IgG4+ cells.
 - Biologic or clinical importance of increased IgG4+ cells in GPA involving head and neck region remains uncertain relative to potential pathogenic relationship between IgG4-related disease and GPA in those cases.
- Diagnosis of GPA is often one of exclusion:
 - Because the histologic findings are often meager, a “negative” biopsy may be of little or no help in excluding GPA.

- Histomorphologic diagnosis may be limited based on the tissue sampling; therefore the clinician must obtain multiple biopsies, especially in areas from the ulcer bed as well as in areas of more viable-appearing tissue.
- In any given biopsy if the histologic features do not support a diagnosis of GPA, but the clinical index of suspicion for GPA is high, additional biopsies may be indicated.
- If the patient has been treated with steroids prior to biopsy, this can suppress the histologic features and make the histologic diagnosis even more difficult and problematic.

Differential Diagnosis

- Infectious diseases:
 - Fungal, mycobacterial, parasitic
- Nonspecific sinusitis/rhinitis
- Collagen vascular disease
- Cocaine use/abuse:
 - Cocaine is a potent vasoconstrictor and with chronic use may result in clinical signs and symptoms as well as mucosal lesions similar to those of GPA.
 - Chronic intranasal inhalation may result in rhinorrhea, nasal obstruction, rhinosinusitis, ulceration, crusting, epistaxis, anosmia, septal perforation, saddle nose deformity, osteocartilaginous necrosis, and/or pain.
 - Not associated with elevated levels of ANCA or PR3
 - Histologic findings may include surface ulceration and crusting with associated acute and chronic inflammation as well as a foreign body (multinucleated) giant cell reaction:
 - Giant cells may engulf and/or surround polarizable material, the latter often used to “cut” or dilute the cocaine.
 - Bacterial and fungal tissue invasion may be identified.
 - Not associated with vasculitis
- Churg-Strauss syndrome (Table 2-2 and Fig. 2-60)
 - Also referred to as allergic granulomatosis and vasculitis, and eosinophilic GPA
 - Characterized by asthma, systemic vasculitis, tissue and peripheral eosinophilia, and nasal manifestations
 - Findings that assist in differentiating from GPA include:
 - Clinical manifestations of peripheral (serum and tissue eosinophilia) may include:
 - Signs and symptoms of eosinophilic pneumonia, eosinophilic gastroenteritis
 - Other nasal manifestations include:
 - Rhinorrhea, rhinosinusitis, nasal polyps, obstruction

TABLE 2-2 Clinicopathologic Comparison: Granulomatosis and Polyangiitis (GPA), Allergic Granulomatosis and Vasculitis,* and Sinonasal Malignant Lymphomas

	GPA	Allergic Granulomatosis and Vasculitis	Extranodal NK/T-Cell Lymphoma, Nasal Type	DLCBL
Gender/age	M > F; fourth-fifth decades; laryngeal GPA affects F > M	M > F; wide age range (third-sixth decades)	M > F; sixth decade; most common in Asians; occurs in Western population but with less frequency	M > F; seventh decade
Location	Localized UADT GPA most common in nasal cavity > paranasal sinuses; other sites may include nasopharynx, larynx (subglottis), oral cavity, trachea, ear, salivary glands	Multisystem disease including pulmonary, nasal, renal, cutaneous, cardiac and nervous system involvement	Generally limited to the sinonasal region; extra-sinonasal involvement occurs and represents a higher stage tumor	Nasal cavity and one or more paranasal sinuses
Symptoms	SNT: sinusitis, with or without purulent rhinorrhea, obstruction, pain, epistaxis, anosmia, headaches Larynx: dyspnea, hoarseness; voice changes Oral: ulcerative lesion Ear: hearing loss, pain	Asthma, allergic rhinitis, evidence of serum and tissue eosinophilia (e.g., eosinophilic pneumonia, eosinophilic gastroenteritis, other), evidence of vasculitis	Destructive process of midfacial region: nasal septal perforation, obstruction, palate destruction, orbital swelling	Nonhealing ulcer, epistaxis, facial swelling, pain, cranial nerve manifestations
Systemic involvement	ELK Classification: E: ear, nose, throat; L: lung; K: kidney; E, EL = limited form GPA; ELK = systemic GPA	Typically patients multisystem involvement although limited forms of disease exist	Majority are localized (stage IE/II/E); May progress to disseminated/systemic involvement	Majority are localized (stage IE/II/E); May progress to disseminated/systemic involvement
Serology	ANCA and PR3 positive: • Increased in primary disease and recurrent disease • (c-ANCA more specific than p-ANCA)	ANCA and PR3 levels may or may not be present; peripheral eosinophilia; may be associated with anti-myeloperoxidase (MPO) ANCA	ANCA and PR3 negative; no specific serologic marker(s)	ANCA and PR3 negative; no specific serologic marker(s)
Histology	Polymorphous (benign) cellular infiltrate; vasculitis; ischemic-type necrosis; isolated multinucleated giant cells (not well-formed granulomas); negative cultures and stains for organisms	Polymorphous (benign) cellular infiltrate, predominantly eosinophils; vasculitis that may be a granulomatous vasculitis (multinucleated giant cells in the wall of involved blood vessels); eosinophilic microabscesses; negative cultures and stains for organisms	Overtly malignant cellular infiltrate but in early phases malignant cells may not be overtly identifiable; angiocentricity and angioinvasion; ischemic-type necrosis; no giant cells or granulomas; negative cultures and stains for organisms	Diffuse dyscohesive cellular proliferation of medium to large cells with large round to oval vesicular (noncleaved) nuclei, prominent nucleoli, increased mitotic activity and necrosis
IHC	LCA, B- and T-cell markers, kappa and lambda light chains	LCA, B- and T-cell markers	CD3 cytoplasmic, CD2, CD56 positive; T-cell markers (CD3, others) positive; cytotoxic granule markers (granzyme B, TIA-1, perforin) positive	LCA and B-cell markers (CD20, CD79) positive; p63 may positive (focal to diffuse)
EBV	Negative	Negative	Strong association	No to weak association

TABLE 2-2 Clinicopathologic Comparison: Granulomatosis and Polyangiitis (GPA), Allergic Granulomatosis and Vasculitis,* and Sinonasal Malignant Lymphomas—cont'd

	GPA	Allergic Granulomatosis and Vasculitis	Extranodal NK/T-Cell Lymphoma, Nasal Type	DLCBL
Treatment	Cyclophosphamide and prednisone	Systemic corticosteroids	Radiotherapy for localized disease; chemotherapy for disseminated disease	Radiotherapy and/or chemotherapy
Prognosis	Limited disease associated with a good to excellent prognosis and occasional spontaneous remissions; mortality related to complications of renal and pulmonary involvement	62% 5-year survival; increased morbidity and mortality due to cardiac involvement resulting in CHF or MI	5-year survival for Stage I is approximately 50%; local recurrence/relapse and systemic failure common	Dependent on stage; 5-year survival rates vary in the literature from 29% to 80%

ANCA, Antineutrophil cytoplasmic antibodies; CHF, congestive heart failure; DLCBL, diffuse large cell B-cell lymphoma; EBV, Epstein-Barr virus; F, female; GPA, granulomatosis and polyangiitis (formerly referred to as Wegener granulomatosis); IHC, immunohistochemistry; M, male; MI, myocardial infarction; NK, natural killer; PR3, proteinase 3; SNT, sinonasal tract; UADT, upper aerodigestive tract.

*Also known as Churg-Strauss syndrome as well as eosinophilic granulomatosis and polyangiitis.

**Fig. 2-60. Sinonasal Churg-Strauss syndrome.**

A, Histologic changes include vasculitis with transmural inflammation. **B**, At higher magnification the inflammatory cell infiltrate includes an admixture of eosinophils, neutrophils, lymphocytes, and plasma cells, and an isolated giant cell (*lower right*). **C**, Within the submucosa the inflammatory cell infiltrate predominantly includes eosinophils, as well as neutrophils, lymphocytes, plasma cells, and multinucleated giant cells; eosinophilic and neutrophilic microabscess formation can also be seen (not shown). This is an unusual diagnosis requiring detailed clinical correlation as well as special stains to exclude the presence of infectious disease.

- Nasal crusting and septal perforation (similar to GPA) may occur.
- Nasal manifestations reported in a majority of patients with this disease
- Constitutional findings include malaise, fever, weight loss, night sweats, arthralgia(s), and myalgia(s).
- Renal involvement results in hypertension but usually not as clinically aggressive as seen in GPA.
- Pulmonary involvement rarely results in cavitation.
- Cutaneous (maculopapular eruptions, nodules, and purpura), cardiac (pericarditis, myocardial infarction), and nervous system involvement (neuropathy, cerebral hemorrhage, infarction)
- Limited form of disease exists, lacking full clinical and pathologic features, and without systemic involvement and with limited sites of involvement
- ANCA levels may or may not be present:
 - Because elevated ANCA levels have been reported in Churg-Strauss syndrome, this finding cannot be used to differentiate Churg-Strauss syndrome from GPA.
 - May be associated with anti-myeloperoxidase (MPO) ANCA
- Additional laboratory findings may include increased serum IgE, anemia (normochromic, normocytic), and elevated erythrocyte sedimentation rate.
- Serum IgG4 levels are markedly elevated in active Churg-Strauss syndrome and correlate with the number of organ manifestations and disease activity.
- Histologic findings include:
 - Vasculitis of small to medium-sized blood vessels with transmural inflammatory cell infiltrate (angioinvasion); vasculitis is present in the majority of cases (70%).
 - Infiltrate predominantly includes eosinophils, but lymphocytes and neutrophils may be present in small numbers; tissue eosinophilia is found in approximately 57% of cases.
 - Granulomatous vasculitis may be seen and is characterized by the presence of multinucleated giant cells found within the vessel wall; the latter may or may not be associated with fibrinoid necrosis; granulomas are found in approximately 38% of cases.
 - Eosinophilic microabscesses (not related to blood vessels) may be present.
 - Likelihood of finding vasculitis, granulomas, and tissue eosinophilia in a single biopsy is small (less than 15% of cases).
- Systemic corticosteroids are the preferred treatment.
- In patients resistant to standard therapy, rituximab may be used and has been shown to be effective and safe.
- 5-year survival rate of 62%
- Relapses are frequent, especially in patients with anti-myeloperoxidase antibodies and baseline eosinophilia $<3000/\text{mm}^3$.
- Death results from cardiac involvement with congestive heart failure or myocardial infarction.
- IgG4-related disease:
 - See Section 6, Salivary Glands, for more detailed discussion.
 - Increased IgG4+ cells not uncommonly present sinonasal (or orbital/periorbital) GPA, which could pose a diagnostic pitfall
 - GPA in other organs and controls does not show increased IgG4+ cells.
 - Biologic or clinical importance of increased IgG4+ cells in GPA cases involving head and neck region is uncertain but raises potential pathogenic relationship between IgG4-related diseases and GPA.
- Nasal-type NK/T cell lymphoma ([Table 2-2](#)):
 - Cytologic characteristics of the lymphoid infiltrate often permit distinction between GPA and NK/T cell lymphoma.
 - Lymphoid infiltrates in GPA lack an appreciable degree of cytologic atypia; atypia is characteristic of the tumor cells of malignant lymphoma.
 - In view of the fact that some degree of subjectivity may enter into the recognition of lymphoid atypia by light microscopic features alone, immunohistochemical, in situ hybridization, and/or molecular biologic studies may be helpful in a diagnosis of nasal-type NK/T cell lymphoma (see next chapter).

Treatment and Prognosis

- Once the diagnosis and extent of disease is determined, most patients with GPA receive a combination of cyclophosphamide and prednisone:
 - 75% complete remission rate may be achieved with this treatment regimen, although patients may experience one or more relapses from 3 months to 16 years after complete remission.
 - Patients with GPA who experience remission are not necessarily cured of disease and are at risk for recurrences throughout their life.
- Rituximab can be used in patients with refractory or relapsing disease.
- Patients with limited disease are treated with antibiotics (trimethoprim-sulfamethoxazole).
- Steroid therapy may alter the histomorphology, with reduction or elimination of the vasculitic component.

- GPA surgical intervention may be required in treating patients with progression of disease in the upper aerodigestive tract:
 - Frequent surgical intervention may be required.
 - Endoscopic surgical technique offers safe and successful approach for treatment of subglottic stenosis due to GPA.
 - Patients with fulminating disease, especially with renal failure, are treated with high doses of prednisone:
 - This treatment is maintained until the disease is under control as evidenced by improved ESR, serum creatinine, or ANCA titer, at which time cyclophosphamide therapy is begun.
 - Prednisone is continued until the cyclophosphamide can take effect, which occurs approximately 2 to 3 weeks after initiation of therapy.
 - Limited GPA responds well to cyclophosphamide and/or steroid therapy and has a good prognosis.
 - Mortality rates of up to 28% have been reported:
 - Major source of morbidity and mortality is renal or pulmonary insufficiency and/or complications of therapy (e.g., sepsis, drug-induced malignancies).
 - Occasionally, spontaneous remissions may be seen with milder forms of disease when only one or a few organs are involved (but not the kidneys).
- Although uncommon, changes of NS can occur in seromucous glands of sinonasal tract similar to that seen in relationship to oral cavity minor salivary glands (a more frequent site of occurrence).
 - Similar to NS of other locations, sinonasal NS can easily be misinterpreted as carcinoma:
 - Usually the metaplasia is a small focus and seldom is it as extensive as has sometimes been found in the lesions of the palate.
 - Histologically, the findings are similar to those found in more common locations.

EOSINOPHILIC ANGIOCENTRIC FIBROSIS (EAF) (Fig. 2-61)

Definition: Rare chronic sclerosing and fibroinflammatory disorder of the upper aerodigestive tract.

Clinical

- Uncommon lesion
- Postulated to represent the mucosal variant of granuloma faciale owing to:
 - Histologic similarities of early nasal mucosal lesions to those seen in granuloma faciale
 - Concurrent occurrence of EAF and granuloma faciale in approximately 25% of EAF cases
- Much more common in women than in men; occurs in adults over wide age range.
- Sites of involvement include the nasal cavity, larynx (subglottis), orbit, lacrimal gland, and oral cavity (gums):
 - In the nasal cavity affects the septum > lateral wall

NECROTIZING SIALOMETAPLASIA (NS)

- See Section 6, Salivary Glands, for a more complete discussion.

Fig. 2-61. Eosinophilic angiocentric fibrosis.

A and B, The histologic features include an eosinophilic perivascular infiltrate that surrounds and extends into capillaries and venules (eosinophilic angiitis); plasma cells and mature lymphocytes may also be present. In contrast to granulomatosis with polyangiitis, vascular thrombosis and “ischemic” type necrosis are not identified.

- Often unilateral but may be bilateral
- May rarely extend to paranasal sinuses (usually maxillary sinus) or orbit
- Clinical presentation is that of progressive airway obstruction over several years; some patients have associated allergies, including allergic rhinitis, chronic urticaria, sensitivity to penicillin.
- Laboratory findings are nonspecific:
 - ANCA levels are not elevated.
 - No abnormalities reported in erythrocyte sedimentation rate or urinalysis.
- No known cause
- Recent evidence supports including EAF in the spectrum of IgG4-related diseases as evidenced by the presence in patients with EAF of:
 - Serum IgG4 concentration of 1490 mg/dl (normal, 8 to 140 mg/dl)
 - IgG4-positive plasma cells ranging from 43 to 118 per high-power field
 - IgG4:IgG from 0.68 to 0.97

Pathology

- Histologic features described include an early and late phase, both of which can be seen in any given biopsy.
- In early lesions there is an eosinophilic perivascular infiltrate in the lamina propria:
 - Eosinophils surround and extend into capillaries and venules (eosinophilic angiitis).
 - Plasma cells and mature lymphocytes may also be present.
 - Thrombosis and “ischemic” type necrosis are not identified.
- In late lesions, the most characteristic feature is the presence of dense fibrosis with a layered “onion-skin-type” perivascular fibrosis (angiocentric fibrosis):
 - The fibrosis is hypocellular, but areas of mixed inflammatory cells remain, including eosinophils.
- Cytologic atypia is not present.
- No microorganisms, granulomatous inflammation, or giant cells are seen.

- Histochemistry:
 - Special stains for microorganisms are negative.
- Immunohistochemistry:
 - Plasma cells are polyclonal.
 - Lymphocytes are predominantly T-cells.

Differential Diagnosis

- Infectious disease
- Granulomatosis with polyangiitis (formerly Wegener granulomatosis)
- Churg-Strauss syndrome
- Fibromatosis
- Subglottic stenosis for cases involving the larynx
- Nasal-type NK/T cell lymphoma

Treatment and Prognosis

- Surgery may be required in the patients with airway obstruction to create a patent airway by excising the area of stenosis.
- Corticosteroids and antihistamines do not appear to be effective modes of treatment.
- Disease progression stabilizes over time but typically not prior to the development of airway obstruction.

IGG4-RELATED DISEASES

- Relatively recently described group of diseases with characteristic morphology that may be systemic with multiorgan involvement or localized to specific anatomic sites
- May occur in the sinonasal tract independent of involvement of more common nonhead and non-neck sites of occurrence (i.e., pancreas) and/or more common head and neck sites of occurrence (i.e., submandibular gland)
- See Section 6, Salivary Glands, for a more complete discussion.

Embryology, Anatomy, and Histology of the Oral Cavity

EMBRYOLOGY OF THE ORAL CAVITY

- Primitive mouth or stomodeum develops partly from the surface ectoderm and partly from the endoderm of the cranial end of the foregut (the future site of the pharynx):
 - Initially, the oropharyngeal membrane separates these structures, but at the end of the fourth week of gestation the oropharyngeal membrane disappears, allowing for direct communication of the mouth with the pharynx.
- Most of the epithelium of the oral cavity (lips, gums, palate) are of ectodermal origin.
- Epithelium of tongue varies in its development:
 - Anterior two thirds of oral tongue is of ectodermal origin, developing from the tuberculum impar (median tongue bud or swelling), and is of first branchial arch derivation.
 - Posterior or pharyngeal portion of the tongue is of endodermal origin, developing from the hypobranchial eminence, and is of third branchial arch derivation.
- Muscles of mastication (temporalis, masseter, and medial and lateral pterygoids) are derived from the first branchial arch (mandibular arch).
- Mandible is formed from the mandibular prominence of the first branchial arch.
- Maxilla, zygomatic bone, and squamous part of the temporal bone derive from the maxillary prominence of the first branchial arch.
- Nerves:
 - Trigeminal nerve (V) (maxillary and mandibular branches) arises from the first branchial arch.
 - Facial nerve (VII) arises from the second branchial arch.
 - Glossopharyngeal nerve (IX) arises from the third branchial arch.
 - Vagus nerve (X) arises from the fourth branchial arch.

CONTENTS OF THE ORAL CAVITY

- Structures within the anatomic confines of the oral cavity (Fig. 4-1) include:

- Lips:
 - Mucosal lip begins at the junction of the vermilion border with the skin and includes only the vermilion surface or that portion of the lip that comes in contact with the opposing lip.
 - Vermilion border represents the junction between the skin and the oral mucosa.
- Oral vestibule:
 - Slit-like space between the lips or cheeks on one side and teeth on the other side
 - When teeth occlude the vestibule is a closed space that only communicates with the oral cavity proper in retromolar region behind the last molar tooth on each side.
 - Mucosa that covers the alveolus of the jaw is reflected onto the lips and cheeks; a trough or sulcus is formed called the fornix vestibuli.
 - In midline there are upper and lower labial frena or frenula.
 - Upper frenula attached well below alveolar crest
- Buccal mucosa (cheeks):
 - Includes all the membrane lining of the inner surface of the cheeks and lips from the line of contact of the opposing lips to the line of attachment of mucosa of the alveolar ridge (upper and lower) and pterygomandibular raphe
- Floor of mouth:
 - Semilunar or horseshoe-shaped area situated beneath the movable tongue between the upper alveolar ridge and the mucous membrane covering the palatine process of the maxillary palatine bones
 - Extends from the inner surface of the superior alveolar ridge to the posterior edge of the palatine bone
 - A fold of tissue, lingual frenulum, extends from the inferior surface of tongue near the base of the tongue.
 - Submandibular ducts open into the mouth at the sublingual papilla (caruncle), which is a large positioned protuberance at the base of the tongue.
- Retromolar trigone:
 - Attached mucosa overlying the ascending ramus of the mandible from the level of the

Fig. 4-1. Contents of the oral cavity.

(From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Figure 27-1, p 1618.)

posterior surface of the last molar tooth to the apex superiorly, adjacent to the tuberosity of the maxilla

- Tongue (Fig. 4-2):
 - Highly muscular organ of deglutition, taste, and speech
 - Attached by muscles to hyoid bone, mandible, styloid process, soft palate, and pharyngeal wall
 - Has root, apex, curved dorsum, and inferior (ventral) surface
 - Dorsal tongue:
 - Represents the superior surface related to hard and soft palates
 - Located in floor of the oral cavity
 - Generally convex in all directions at rest
 - Divided by V-shaped sulcus terminalis into anterior (oral or presulcal) part, which faces upward, and posterior (pharyngeal or post-sulcal) part, which faces posterior
 - Oral (presulcal) tongue:
 - Anterior two thirds of tongue lying in floor of oral cavity
 - Freely mobile portion
 - Extending anteriorly from the line of circumvallate papillae to the undersurface of the tongue at the junction of the floor of the mouth
 - Covered by numerous papillae, some of which bear taste buds
 - Pharyngeal (postsulcal) part:
 - Posterior one third of tongue representing its base lying posterior to palatoglossal arches

- Forms anterior wall of oropharynx
- Mucosa reflects laterally onto palatine tonsils and pharyngeal wall and posteriorly onto the epiglottis by glossoepiglottic folds surrounding two depressions or valleculae
- Devoid of papillae
- Underlying lymphoid nodules embedded in submucosa collectively referred to as lingual tonsil
- In situations in which the thyroid does not migrate during development, it remains in postsulcal part of the tongue (lingual thyroid, see Section 8)
- Ventral surface of tongue:
 - Represents the undersurface (nonvillous ventral surface)
 - Visible when the tip of the tongue is turned upward
- Palatine bone:
 - Posteriorly placed in nasal cavity between maxillae and pterygoid processes of the sphenoid bones
 - Contribute to:
 - Floor and lateral walls of the nose
 - Floor of the orbit
 - Hard palate
 - Pterygopalatine and pterygoid fossae
 - Inferior orbital fissure
 - Each palatine bone has:
 - Two plates (horizontal and perpendicular) arranged as L-shaped
 - Three processes: pyramidal, orbital, and sphenoidal
- Hard palate:
 - Semilunar area between the upper alveolar ridge and the mucous membrane covering the palatine process of the maxillary palatine bones
 - Extends from the inner surface of the superior alveolar ridge to the posterior edge of the palatine bone
- Soft palate:
 - See Section 3, Pharynx.
- Gingivae (gums):
 - Lining mucosa of the (inner) cheeks
- Gnathic (jaw) bones:
 - Include maxilla and mandible
- Maxilla:
 - Largest of facial bones (other than the mandible) that jointly form the whole of the upper jaw
 - Each maxillary bone forms the greater part of the floor and lateral wall of the nasal cavity, floor of orbit, contributes to the infratemporal and pterygopalatine fossae and bounds inferior orbital and pterygomaxillary fissures

**Fig. 4-2. The tongue.**

A, Dorsum of the tongue. **B**, Ventral aspect of the tongue including the floor of mouth. (**A**, From *Standring S: Gray's anatomy, ed 40, Edinburgh, 2009, Elsevier Churchill Livingstone, p 503, Figure 30.5*. **B**, From *Standring S: Gray's anatomy, ed 40, Edinburgh, 2009, Elsevier Churchill Livingstone, Figure 30.4, p 502*.)

- Each maxilla has a body; four processes including:
 - Zygomatic
 - Frontal
 - Alveolar
 - Palatine
- Mandible:
 - Largest and strongest bone of the face wholly forming the lower jaw
 - Composed of:
 - Horizontally curved body that is convex forward
 - Two broad rami that ascend posteriorly
 - Body of mandible supports mandibular teeth within alveolar process
 - Rami bear coronoid and condylar processes:
 - Each condyle articulate with adjacent temporal bone at the temporomandibular joint
- Synovial joint between the articular fossa (referred to as glenoid or mandibular fossa), temporal bone above and mandibular condyle
- Articular surface lined by fibrocartilage rather than hyaline cartilage
- Alveolar bone
 - Part of maxilla or mandible that supports and protects the teeth
 - Arbitrary boundary at level of root apices of the teeth separates alveolar processes from the body of the mandible and/or maxilla.
 - Alveolar ridges (lower and upper):
 - Bony structures supporting teeth and periodontal tissue arise from floor of mouth and descend from hard palate
 - Lower alveolar ridge:
 - Mucosa overlying the alveolar process of the maxilla that extends from the line of

attachment of the mucosa in the upper gingival buccal gutter to the junction of the hard palate

- ◻ Posterior margin is the upper end of the pterygopalatine arch.
- Lower alveolar ridge:
 - Mucosa overlying the alveolar process of the mandible that extends from the line of attachment of mucosa in the buccal gutter to the line of free mucosa of the floor of the mouth
 - Posteriorly, it extends to the ascending ramus of the mandible.
- Teeth (Fig. 4-3):
 - Composed of tubular dentin capped by thin shell of very hard but brittle enamel in tooth crown
 - Tooth root surrounded by cementum
 - Periodontal membrane attaches to cementum on one side and alveolar bone on the other side.
 - Tooth numbering:
 - Total of 32 teeth
 - American Dental Association system includes numbering of each tooth by one number from 1 to 32, starting from right maxillary third molar moving clockwise
- Periodontal ligament
 - Functions to support the teeth, generate force of tooth eruption, and provide sensory information about tooth position and forces to facilitate reflex jaw activity
 - Dense fibrous connective tissue 0.2 mm wide containing cells associated with development and maintenance of alveolar bone (osteoblasts and osteoclasts) and cementum (cementoblasts and odontoclasts)
 - Contains network of epithelial cells (epithelial cell rests of Malassez), which are embryologic remnants of an epithelial root sheath
 - No evident function but may give rise to dental cysts

ANATOMIC BORDERS OF THE ORAL CAVITY

- Anterior: vermillion border of the lips
- Posterior: line drawn from the junction of the hard and soft palate to the circumvallate papillae of the tongue
- Superior: hard palate until its junction with the soft palate
- Inferior: anterior two thirds of the tongue to the line of the circumvallate papillae
- Lateral: buccal mucosa of the cheeks

Histology (Figs. 4-4 and 4-5)

- Histology of epithelial surfaces of oral cavity mucosa is detailed in Table 4-1
- Tongue:
 - Dorsal tongue:
 - Anterior two thirds (specialized oral mucosa):
 - Keratinized squamous epithelium covered with numerous small mucosal projections forming papillae with slender rete ridges
 - According to shape papillae may appear filiform, fungiform, foliate, or circumvallate
 - Majority are filiform papillae appearing as conical projections of keratinized epithelium
 - Fungiform papillae appear as rounded elevations of nonkeratinized epithelium mainly on lingual margin but also irregularly on dorsal surface
 - Foliate papillae located posteriorly along sides of tongue appearing as leaf-like mucosal ridges covered by nonkeratinized epithelium
 - Circumvallate papillae present at junction of anterior two thirds and posterior one third of tongue representing the largest papillae arranged in a V-shape located immediately anterior to sulcus terminalis covered by nonkeratinized epithelium
 - Taste buds
 - Pale, oval bodies within the papillae epithelium
 - Numerous within circumvallate papillae
 - Less numerous in fungiform and foliate papillae as well as elsewhere along dorsal and lateral aspects of tongue
 - Intraepithelial localization appearing as lighter staining structures oriented at a right angle to the surface composed of spindle cells with elongated nuclei
 - Composed of three cell types:
 - ◻ Gustatory or taste cells
 - ◻ Supporting or sustentacular cells
 - ◻ Basal cells
 - Immunoreactive for cytokeratins (CAM5.2, CK18)
 - Ventral tongue:
 - Stratified nonkeratinized squamous epithelium with short, blunt rete ridges
 - Submucosa merges with connective tissue intersecting with ventral muscle bundles
 - Papillae seen on dorsal tongue are absent on ventral tongue surface
- Minor salivary glands: (see Section 7, Salivary Glands, for histologic illustrations)
 - Seen throughout the oral cavity
 - Appear as scattered unencapsulated small lobules within the oral cavity mucosa and submucosa

Fig. 4-3. Teeth.

A, Upper dental arch. **B**, Lower dental arch. **C**, Tooth numbering system. (**A**, From Standring S: *Gray's anatomy*, ed 40, Edinburgh, 2009, Elsevier Churchill Livingstone, Figure 30.14A, p 509. **B**, From Standring S: *Gray's anatomy*, ed 40, Edinburgh, 2009, Elsevier Churchill Livingstone, Figure 30.14B, p 509. **C**, From Woo SB: *Oral pathology*, Philadelphia, 2012, Elsevier, Figure 1-12, p 6.)

Fig. 4-4. Histology of oral mucosa.

A, Normal buccal mucosa composed of nonkeratinized stratified squamous epithelium including cells with vacuolated appearing cytoplasm due to the presence of glycogen and broad rete ridges. **B**, Normal floor of mouth composed of thin stratified squamous epithelium with poorly formed rete ridges. **C**, Normal hard palate mucosa composed of a thin layer of orthokeratinized epithelium with thin granular cell layer. In this location submucosal mucous glands are identified in a dense lamina propria (not shown).

Fig. 4-5. Histology of oral mucosa.

A, Dorsal aspect of the tongue, in particular the anterior portion, is characterized by the presence of numerous mucosal projections forming papillae; these papillae are absent on the ventral surface. **B**, Taste buds located along the dorsal and lateral aspects of the tongue appear as pale, oval bodies within the papillae epithelium.

TABLE 4-1 Oral Mucosa: Histologic Features

Site	Histology
Buccal and labial mucosa (contiguous structures)	Thick, nonkeratinizing, stratified squamous epithelium with broad, tapered rete ridges
Dorsal tongue	Moderate to thick keratinized squamous epithelium with parakeratosis
Floor of mouth and ventral tongue (contiguous structures and histology similar to soft palate)	Thin, nonkeratinizing, stratified squamous epithelium with short or poorly formed rete ridges Serous minor salivary glands identified in anterior ventral tongue (glands of Blandin and Nuhn) and posterior ventral tongue (von Ebner glands)
Gingiva, attached (histology similar to hard palate)	Thin layer of orthokeratin with thin granular layer of nonkeratinizing stratified squamous epithelium with poorly formed rete ridges; rete ridges tend to be more tapered and slender as compared with hard palate May contain odontogenic epithelial rests (rests of Serres)
Gingiva, nonattached	Nonkeratinized epithelium
Hard palate (histology similar to attached gingiva)	Thin layer of orthokeratin with thin granular layer of nonkeratinizing stratified squamous epithelium with poorly formed rete ridges; dense lamina propria; submucosal minor salivary glands present
Soft palate	Thin nonkeratinizing stratified squamous epithelium with short or poorly formed rete ridges

- Intramuscular location seen in association with the tongue and lips
- Minor salivary glands in the tongue are located:
 - In anterior ventral portion (referred to as Blandin or Nuhn glands) composed of mixed serous and mucous types
 - In region of the circumvallate papillae on the posterior and lateral portion (referred to as von Ebner glands) composed of pure serous type
 - In remainder of the oral cavity the glands are mixed seromucous with mucous glands predominating and in area of hard palate are pure mucous glands
 - Minor salivary glands are present in the retro-molar mandibular ridge but the anterior hard palate and gingiva are typically devoid of minor salivary glands.
- Nonepithelial intraepithelial cells:
 - Nonepithelial cells present in oral mucosa include:
 - Melanocytes:
 - Located in basal layer
 - Most common in gingiva but also present in lips, palate, buccal mucosa
 - Immunoreactivity includes S100 protein and melanocytic markers
 - Langerhans (dendritic) cells:
 - Mostly located in suprabasal layers
 - Play role in immune response
 - Dendritic nature cannot be recognized by routine staining
 - Immunoreactivity includes S100 protein, CD1a
 - Dendritic processes best seen following S100 protein staining
 - Merkel cells:
 - Located in basal layer individually or in clusters
 - Represent neuroendocrine cells
 - Not recognized by routine staining
 - Immunoreactivity for neuroendocrine markers (e.g., synaptophysin, chromogranin), S100 protein, neuron-specific enolase, cytokeratins (AE1/AE3, CAM5.2, CK20)
 - Lymphocytes
- Juxtaoral organ of Chievitz (Fig. 4-6):
 - Well-delineated normal microscopic structure of uncertain function normally situated at the angle of the mandible, bilaterally, near the buccotemporal space:
 - Recent evidence supports possible neurosecretory or neuroreceptor function
 - Multilobulated round to elongated nests of squamoid epithelial cells embedded in a fibrous stroma rich in small peripheral nerves:
 - More central cells are nonkeratinizing with identifiable intercellular bridges composed of uniform, bland-appearing nuclei, eosinophilic to clear cytoplasm and inconspicuous nucleoli.
 - More peripheral cells are basaloid appearing with nuclear palisading
 - Occasionally duct-like lumens may be identified
 - Delineated/prominent basement membrane is present around the squamoid cell nests.
 - Absence of keratinization and/or keratohyaline granules
 - Melanin pigment may be identified.

Fig. 4-6. Juxtaoral organ of Chievitz.

A, Multilobulated round nests of squamoid epithelial cells within a fibroconnective tissue stroma. **B**, Nonkeratinizing cells composed of uniform, bland-appearing nuclei, eosinophilic to clear cytoplasm, and inconspicuous nucleoli. **C**, The cell nests lie in close proximity to small peripheral nerves; immunoreactivity is present for **(D)** cytokeratin and **(E)** focally for S100 protein; the latter also delineates the small peripheral nerve. Usually, this normal structure is an incidental finding at frozen section or in permanent sections but its presence, squamoid cells, and normal intimate association with small peripheral nerves (branches of the buccal nerve) may result in diagnostic confusion with an invasive neurotropic squamous cell carcinoma (see Figure 7-10 for frozen section appearance of the juxtaoral organ of Chievitz).

- Immunoreactivity may be present for cytokeratin and S100 protein.
- Usually an incidental finding at frozen section (see section on intraoperative consultation at end of this section) or in permanent sections in tissue excised for other reasons:
 - Given histology that includes squamoid cells and normal intimate association with small peripheral nerves (branches of the buccal nerve), diagnostic confusion may arise with an invasive squamous cell carcinoma with neurotropism.

INNERVATION

- Innervation of the oral cavity structures are from cranial nerves V and VII:
 - Fifth nerve branches to the oral cavity include the maxillary nerve (entirely sensory) and the mandibular nerve (sensory and motor); each of these nerves is further divided into various nerve groups that innervate specific oral cavity structures (for more details the reader is referred to specific anatomy text).
 - Cranial nerve VII:
 - Motor root supplies the muscles of the face.
 - Sensory root supplies the taste fibers via the chorda tympani for the presulcal area of the tongue and via the palatine and greater petrosal nerves the soft palate.
- Innervation of the tongue:
 - Motor innervation to the intrinsic muscles of the tongue are supplied by the hypoglossal (XII) nerve.
 - Sensory nerves include:
 - Lingual branch of the mandibular nerve for ordinary sensibility to the anterior tongue
 - Chorda tympani branch of the facial nerve (VII) for taste to the anterior tongue (excluding the circumvallate papillae)
 - Lingual branch of the glossopharyngeal (IX) nerve for taste and general sensibility to the mucous membranes at the base and lateral aspects of the tongue and to the circumvallate papillae
 - Superior laryngeal nerve to the vallecular area (in front of the epiglottis)

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

- Arteries and veins:
 - Arterial supply to the oral cavity structures comes via branches of the internal carotid artery (facial

artery and its branches) and the external carotid artery (lingual and maxillary arteries and their branches).

- Venous drainage from the oral cavity structures flows to the internal jugular vein via the facial vein and pterygoid plexus and to the external jugular vein via numerous smaller veins, including the facial vein and the maxillary vein.
- Lymphatics:
 - Lips:
 - Upper lip: preauricular, infraparotid, submandibular, and submental lymph nodes:
 - Relative absence of anastomotic channels results in ipsilateral drainage.
 - Lower lip, medial portion: submental lymph nodes
 - Lower lip, lateral portion: submandibular lymph nodes

NOTE: Due to numerous anastomotic lymphatic vessels near the midline of the lower lip, lymphatic drainage occurs bilaterally.

- Buccal mucosa:
 - Lymph nodes in the submental and submandibular triangles of the neck
- Alveolar ridges:
 - Buccal aspect: submental and submandibular lymph nodes
- Retromolar trigone:
 - Upper deep cervical lymph nodes
- Floor of mouth:
 - Anterior part to inferior lymph nodes of the upper deep cervical group via the submental lymph nodes
 - All other parts to submandibular and upper deep cervical lymph nodes
- Tongue:
 - Lymphatics arise from an extensive submucosal plexus with ultimate drainage to the deep cervical lymph nodes.
- Hard palate:
 - Upper deep cervical and retropharyngeal lymph nodes
- Gingiva:
 - Upper gums and lower posterior part: submandibular lymph nodes
 - Lower anterior part: submental lymph nodes

Non-Neoplastic Lesions of the Oral Cavity

CLASSIFICATION OF NON-NEOPLASTIC LESIONS OF THE ORAL CAVITY (Box 5-1)

BOX 5-1 Classification of Non-Neoplastic Lesions of the Oral Cavity

Developmental Cystic Anomalies

Nonodontogenic Cysts

- Nasopalatine duct cyst
- Median palatal cyst
- Nasolabial cyst
- Surgically ciliated cyst
- Others

Nonodontogenic, Nondevelopmental Cysts

- Mucocoeles (mucus extravasation phenomenon; mucus retention cyst, ranula)
- Oral lymphoepithelial cyst
- Simple bone cyst

Odontogenic Developmental Cysts

- Dentigerous cyst
- Eruption cyst
- Lateral periodontal cyst
- Botryoid odontogenic cyst
- Glandular odontogenic cyst
- Gingival cyst
- Primordial cyst

Odontogenic Nondevelopmental Cysts

- Radicular or periapical cyst
- Residual cyst
- Buccal bifurcation cyst
- Paradental cyst

Hamartomas and Choristomas

- Fordyce granules
- Others (e.g., osseous, cartilaginous, glial, and gastrointestinal)
- Ectopias (e.g., lingual thyroid, others)

Infectious and Related Diseases or Lesions

- Fungal
- Viral
- Bacterial
- Mycobacterial
- Protozoal
- Others

Reactive, Inflammatory, and Tumor-like Lesions

- Epithelial reactive lesions (e.g., verrucae, focal epithelial hyperplasia, pseudoepitheliomatous hyperplasia, necrotizing sialometaplasia, others)
- Mesenchymal lesions (e.g., irritation fibromas, oral submucous fibrosis, gingival fibromatosis, others)
- Non-neoplastic osseous lesions (e.g., giant cell granuloma, aneurysmal bone cyst, others)
- Autoimmune, allergic, systemic, cutaneous-type lesions (e.g., granulomatosis with polyangiitis, recurrent aphthous stomatitis, oral lichen planus, others)

CYSTIC (NON-NEOPLASTIC) LESIONS OF THE ORAL CAVITY

- Cystic lesions of the oral cavity represent a diverse group of lesions listed in Box 5-2.
- Cysts of these anatomic sites include nonodontogenic and odontogenic cysts:
 - Both categories include developmental and non-developmental cysts.
- Developmental cysts form for no clinically apparent reason.
 - Nasolabial cyst
 - Surgically ciliated cyst
- The reader is referred to other texts for a discussion of these lesions.

NONODONTOGENIC DEVELOPMENTAL CYSTS

- Oral cavity developmental cysts include:
 - Nasopalatine duct cyst
 - Median palatal cyst

NONODONTOGENIC NONDEVELOPMENTAL CYSTS

- Oral cavity nondevelopmental cysts include:
 - Mucocoele:
 - Mucus extravasation phenomenon, mucus retention cyst, ranula
 - Lymphoepithelial cyst
 - Simple bone cyst

BOX 5-2 Selective Oral Cavity Autoimmune, Systemic, Cutaneous-Type Diseases

- Aphthous stomatitis
- Behçet disease
- Crohn disease
- Dermatitis herpetiformis
- Erythema multiforme
- Granulomatosis with polyangiitis
- Lichen planus
- Pemphigus
- Pemphigoid
- Systemic lupus erythematosus
- Others

- Salivary gland mucocele is a general term used to describe minor salivary gland lesions resulting from obstruction secondary to a mucous plug or intraluminal sialolith, resulting in a mucus retention cyst, or due to trauma resulting in mucus extravasation phenomenon.
- For a more detailed discussion on mucus extravasation phenomenon, mucus retention cyst, and ranulas see Section 6, Salivary Glands.

Oral Lymphoepithelial Cyst (Fig. 5-1)

Definition: Squamous epithelial-lined cystic cavity with an associated benign lymphoid infiltrate in the cyst wall analogous to lymphoepithelial cysts that occur in various anatomic locations, such as salivary gland lymphoepithelial cyst, cervical lymphoepithelial cyst, and pancreatic lymphoepithelial cyst.

Synonym: Benign lymphoepithelial cyst

Clinical

- More common in men than in women; occur over a wide age range with a mean age of occurrence in the fourth decade
- Most common on the floor of the mouth; may also be found on the ventral tongue, posterolateral tongue, soft palate, palatine pillar, and buccal vestibule
- Clinical presentation is that of an asymptomatic swelling
- Cause:
 - No known cause(s)
 - Association with EBV or HIV has not been established.

Pathology**Gross**

- Usually a submucosal, freely mobile nodular mass with a slightly yellow color; overlying mucosa is normal or slightly telangiectatic
- Diameter of the lesions may range from 0.1 to 1.0 cm

Fig. 5-1. Oral lymphoepithelial cyst.

A and B, Unilocular cyst filled with keratin debris lined by stratified squamous epithelium and characterized by the presence of lymphocytic infiltrate with lymphoid follicles in the cyst wall.

Histology

- Characteristically composed of a well-circumscribed, benign, unilocular epithelial-lined cyst:
 - Cyst lumen is lined by stratified or simple squamous epithelium with transition between the two cell types.
 - Cyst does not form complex loculations.
- Cyst wall is characterized by the presence of benign lymphoid follicular hyperplasia:
 - Lymphoid follicles are usually easily identified and may bulge into the luminal surface.
 - Germinal center formation may or may not be present.
 - Focal exocytosis of the lymphocytes into the epithelial lining may be present.
- Lumen may be filled with keratin, mucoid material sparsely interspersed with polymorphonuclear leukocytes and histiocytes, or empty:
 - Occasionally, bacterial colonization may be seen in the cystic space.

- Lumen may be dilated or collapsed.
- Connection to the surface may be found in some cases.

Differential Diagnosis

- Salivary duct cyst
- Squamous cell carcinoma:
 - Rarely oral lymphoepithelial cyst may coexist with squamous cell carcinoma.
- Malignant lymphoma

Treatment and Prognosis

- Complete surgical excision is curative.

ODONTOGENIC CYSTS

Definition: Cysts derived from the various components of the dental apparatus.

- Include developmental and nondevelopmental cysts
- Odontogenic developmental cysts include:
 - Dentigerous cyst:
 - Eruption cyst
 - Lateral periodontal cyst:
 - Botryoid cyst
 - Glandular odontogenic cyst
 - Gingival cyst
 - Primordial cyst
- Odontogenic nondevelopmental cysts include:
 - Radicular or periapical cyst
 - Residual cyst
 - Buccal bifurcation cyst
 - Paradental cyst

- Complete coverage of odontogenic cysts is beyond the scope of this text; the reader is referred to other texts that cover the full clinicopathologic spectrum of odontogenic cystic lesions.
- The following discussion is limited to a few of the more common odontogenic cysts that the surgical pathologist may be confronted with in daily practice.
- Odontogenic keratocyst is, according to the World Health Organization 2005 Working Group, now considered as a bona fide neoplasm and is discussed in Chapter 6 under Odontogenic Neoplasms.

ODONTOGENIC DEVELOPMENTAL CYSTS

Dentigerous Cyst (Figs. 5-2 and 5-3)

Definition: Nonkeratinizing cyst that develops in association with the crown of an unerupted or impacted tooth.

Synonym: Follicular cyst

Clinical

- Most common developmental odontogenic cyst representing up to approximately 20% to 25% of all odontogenic cysts
- More common in men than in women; most frequent in the second through fourth decades of life
- Always associated with the crown of an impacted or unerupted tooth:
 - Permanent teeth are affected.
 - Rarely affect primary teeth

Fig. 5-2. Dentigerous cyst.

Left panel: An unerupted tooth is associated with the cyst (arrow). Right panel: Gross specimen. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 4-238, p 375.)

Fig. 5-3. Dentigerous cyst.

A, Cyst lining composed of thin layer of cuboidal-appearing epithelium with eosinophilic cytoplasm. **B**, Mucous cells (*arrowheads*) can be seen in the cyst lining epithelium. **C**, Fibromyxomatous stroma in dentigerous cyst may be misinterpreted as odontogenic myxoma. **D**, Epithelial odontogenic rests in the cyst wall. **E**, In inflamed cysts the epithelial component may become thicker (hyperplastic) and have a more squamous appearance. **F**, Rushton body formation appearing as hyalinized, eosinophilic, angulated, linear, or curved foci within epithelium can be seen; these formations are not unique to dentigerous cyst and can be seen in other odontogenic lesions (e.g., radicular cyst, odontogenic keratocyst).

- Most commonly affects:
 - Mandibular third molar
 - Maxillary canines and molars
 - Mandibular second molars
- Usually asymptomatic; symptoms related to continuous expansion of the cyst, including displacement of teeth, facial asymmetry:
 - With progression and expansion including bone, pain, numbness, and paresthesia may develop due to pressure on nerves
 - Superimposed infection may result in associated pain.
 - Draining sinus tract may develop with progression (cyst expansion).
- Typically solitary, but may be multifocal:
 - Multiple cysts may occur sporadically or part of mucopolysaccharidoses.
 - Bilateral nonsyndromic cysts may occur.
- Radiology:
 - Well-defined, unilocular radiolucency around crown of impacted tooth:
 - Similar imaging findings found in association with enlarged dental follicle
 - Three radiologic variations identified:
 - Central:
 - Symmetric envelopment by crown of tooth
 - Lateral (paradental):
 - Asymmetric development by the follicle with identification to one side of crown
 - Circumferential:
 - Entire tooth is encircled by radiolucency.
 - Presence of a multilocular lesion more likely represents an odontogenic keratocyst or odontogenic tumor (ameloblastoma, other).
- Cause:
 - Caused by accumulation of fluid (and subsequently glycosaminoglycans from capsular ground substance) between the layers of the reduced enamel epithelium or between the epithelium and the crown of the tooth, causing separation of the follicle from the crown

Pathology

Gross

- Unilocular, smooth-walled cyst

Histology

- In noninflamed cyst, the cyst lining resembles reduced enamel epithelium composed of two to three layers of nonkeratinizing stratified squamous epithelium
- Cyst wall composed of thin fibroconnective tissue:
 - Nests and cords of odontogenic epithelium may be present.
 - Dystrophic calcifications may be present.
 - Connective tissue may be fibrous or fibromyxomatous.

- Under normal situations is devoid of an inflammatory cell component
- If inflamed:
 - Epithelial component may become thicker (hyperplastic), may be squamous in appearance, and/or may show downward expansion of the rete ridges.
 - Cyst wall may show the presence of a mixed chronic inflammatory cell infiltrate, cholesterol clefts/granulomas, and/or a foreign body giant cell reaction.
 - Rushton body formation can be seen:
 - Hyalinized, eosinophilic, angulated, linear, or curved foci within epithelium
 - Not specific for dentigerous cyst as can be seen in other developmental and inflamed cysts, including:
 - Radicular cysts and odontogenic keratocyst
 - Of unknown origin
- In general are devoid of keratinization but rarely may show limited foci of surface keratinization:
 - Occasionally may be orthokeratinized but lacks characteristic features of odontogenic keratocyst
 - In the presence of more extensive surface keratinization may represent an odontogenic keratocyst (see below)
 - Other findings that may be identified in the epithelial component include mucous (goblet) cells and ciliated cells.
- Special stains:
 - Noncontributory to diagnosis

Differential Diagnosis

- Enlarged dental follicle ([Fig. 5-4](#)):
 - Dental follicles are characterized by presence of reduced enamel epithelium, a copious myxoid-appearing stroma with scattered identifiable epithelial (odontogenic cell) nests; the latter may be limited in extent.
- Dental papilla ([Fig. 5-5](#)):
 - Composed of primitive myxoid connective tissue lined by odontoblasts:
 - Histologically identical to odontogenic myxoma
 - Clinical and radiologic correlation reveals that a developing tooth was removed rather than an odontogenic cyst/neoplasm.
- Radicular or periapical cyst (see below)
- Calcifying odontogenic cyst
- Ameloblastoma, unicystic
- Odontogenic adenomatoid tumor
- Squamous odontogenic tumor

Treatment and Prognosis

- Therapy varies depending on the cyst size:
 - Small cyst can be treated by enucleation and removal of the involved tooth.

Fig. 5-4. Dental follicle.

Dental follicle composed of **(A)** reduced enamel epithelium and **(B)** nests of odontogenic epithelium within the stroma. These findings may suggest a diagnosis of dentigerous cyst.

- Larger cyst can be managed by marsupialization.
- Recurrence is uncommon and generally relates to incomplete excision.
- May give rise to various odontogenic tumors, including:
 - Ameloblastoma
 - Odontogenic adenomatoid tumor
 - Intraosseous carcinoma including:
 - Squamous cell carcinoma
 - Mucoepidermoid carcinoma

Eruption Cyst

Definition: Soft tissue variant of dentigerous cyst:

- Represents a dilation of the normal follicular space
- Develops secondary to accumulation of blood or fluid between the tooth crown and an erupting or permanent tooth and the overlying mucosa

Synonym: Eruption hematoma

Fig. 5-5. Dental papilla.

A, Rounded fragment of primitive myxoid tissue (*left*) including odontogenic cell nest (*arrow*) and lined by odontoblasts (*arrowhead*). **B**, Higher magnification of the columnar odontoblastic cell lining and **(C)** odontogenic cell nest within the myxoid connective tissue. These histologic features are identical to those seen in odontogenic myxoma. Clinical and radiologic correlation reveals that a developing tooth was removed rather than an odontogenic cyst/neoplasm.

Clinical

- Occurs almost exclusively in infants and young children
- More common in girls than in boys
- Present as a bluish-appearing firm to fluctuant swelling of the alveolar ridge overlying an erupted tooth
- Usually asymptomatic but if inflamed may be painful and tender
- Unilateral or bilateral cyst:
 - Most common locations include central incisor and primary first molar region.
- Radiology:
 - Associated tooth lies immediately below a soft tissue swelling

Pathology

- Lined by nonkeratinized stratified squamous epithelium with a chronic inflammatory cell infiltrate in the cyst wall
- Cyst epithelial lining may be absent; in such instances the designation eruption hematoma can be used.

Treatment and Prognosis

- Usually resolves spontaneously with eruption of the associated tooth
- Surgical intervention (exposure of tooth with removal of portion of enclosed mucosa) may be required in the presence of infection or resulting delay in the eruption of the involved tooth.

Glandular Odontogenic Cyst (GOC)

(Fig. 5-6)

Definition: Nonkeratinizing cyst in tooth-bearing areas of the jaws lined by cuboidal to columnar epithelial cells and crypt-like and microcystic spaces often lined by mucous cells.

Synonyms: Sialo-odontogenic cyst; mucus-producing cyst; mucoepidermoid odontogenic cyst

Clinical

- More common in males than females; wide age range but most common in fifth through decades
- Most often involves the mandible, in particular anterior portions:
 - Canine region most common for maxillary lesions
- Symptoms include jaw swelling or expansion with or without pain:
 - May be associated with:
 - Tooth displacement or root resorption
 - Impacted tooth
 - Perforation and thinning of cortical plates

- Radiology:
 - Unilocular or multilocular radiolucency with well-defined sclerotic borders

Pathology**Histology**

- Features include:
 - Surface eosinophilic cuboidal cells (“hobnail cells”) present on surface of cyst lining and resemble cuboidal cells of the reduced enamel epithelium that lines dental follicles and dentigerous cysts
 - Intraepithelial microcysts or duct-like spaces lined by a single layer of cuboidal to columnar cells similar to surface cells:
 - Microcysts may be lined by mucous goblet cells.
 - Microcysts may contain mucous pools and eosinophilic material or may appear to be empty.
 - In areas, microcysts may open onto surface of lining epithelium.
 - Apocrine snouting of hobnail cells:
 - Hobnail cells demonstrate “pinching off” of surface similar to decapitation secretion seen in cells that line apocrine gland ducts.
 - Clear or vacuolated cells may be present in the basal and/or parabasal layers.
 - Cells contain glycogen
 - Variable thickness of cyst lining
 - Papillary projections or “tufting” into cyst lumen
 - Papillary projections sometimes are formed by several microcysts opening onto surface of the cyst lining but may also be formed independent of microcyst.
 - Mucous goblet cells may be present singly or in small clusters on the surface or within cyst lining; may also line microcysts.
 - Epithelial spheres or plaque-like thickenings
 - Plaque-like thickenings may have swirled appearance histologically similar to that seen in association with lateral odontogenic cyst and botryoid odontogenic cyst.
 - True cilia on surface of eosinophilic cuboidal cells distinct from apocrine snouting
 - Multiple compartments or cystic spaces similar to those seen in botryoid odontogenic cysts
- Immunohistochemistry:
 - Positive for cytokeratins (CK5/6, CK7)
 - Variable reactivity for calponin
 - Negative for S100 protein and smooth muscle actin
- Cytogenetics and molecular genetics:
 - Absence of *MECT1-MAML2* translocation:
 - Translocation present in salivary gland mucoepidermoid carcinoma and central mucoepidermoid carcinoma

Fig. 5-6. Glandular odontogenic cyst.

A, Low magnification shows a cystic lesion with variably thickness of the lining epithelium. **B**, Cells with eosinophilic-appearing cytoplasm line the cyst surface resembling the cells of the reduced enamel epithelium that line dental follicles and dentigerous cysts. **C**, Intraepithelial microcysts or duct-like spaces (*arrows*) are lined by a layer of cuboidal to columnar cells appearing epithelium similar to surface epithelial cells. **D**, Mucous (goblet) cells are present singly or in small clusters (*arrowheads*). **E**, Mucous (goblet) cells show intracytoplasmic mucin-positive material. **F**, Epithelial spheres or plaque-like thickenings have swirled or whorled appearance (*arrow*); similar epithelial swirls can be seen in with lateral odontogenic cyst and botryoid odontogenic cyst.

Differential Diagnosis

- Central mucoepidermoid carcinoma (CMEC) (Fig. 5-7):

Definition: Malignant epithelial salivary gland neoplasm originating in the jaws, an area normally devoid of salivary gland tissue, and composed of a variable admixture of epidermoid and mucus-secreting cells.

- Predilect to mandible; less often affect maxilla:
 - In mandible, third molar region is most common site
 - In maxilla, molar region is most common site
- May be asymptomatic and identified incidentally in radiologic evaluation as a radiolucent lesion

Fig. 5-7. Central mucoepidermoid carcinoma.

The presence of infiltrative epithelial nests composed of more proliferative (thicker) epithelium, including an admixture of mucocytes (arrows), epidermoid cells, and intermediate cells are findings that assist in the differential diagnosis with glandular odontogenic cyst.

- Symptomatic cases may include swelling, pain, facial asymmetry, or trismus.
- More than 50% associated with an unerupted tooth or a cyst
- Proposed origin includes:
 - Ectopic salivary gland tissue (not favored)
 - Development from odontogenic cyst, which is the favored origin given:
 - Metaplastic cells seen in odontogenic lesions
 - Half of central MECs occur in association with a cyst or an unerupted tooth.
 - Other neoplasms develop from odontogenic cyst.
- Histologic findings (i.e., cellular components) similar to salivary gland tumors:
 - Tend to be histologically low grade
 - Histology similar to glandular odontogenic cyst and histologic differentiation may be problematic resting on:
 - Extent of the cellular proliferation:
 - More proliferative (i.e., thicker) cellularity in CMEC composed of admixture of mucocytes, epidermoid cells, and intermediate cells
 - GOC has thinner epithelium with little tendency to be as proliferative as MEC.
 - Presence of invasive growth:
 - Invasive growth associated with CMEC but not GOC
- Cytogenetics and molecular genetics:
 - *MECT1-MAML2* translocation identified in salivary gland MECs also reported in CMEC
 - Possible relationship of GOC and CMEC proposed, perhaps even GOC representing a precursor lesion to CMEC:
 - Absence of *MECT1-MAML2* translocation in GOC discredits it from being a precursor lesion to GOC.
- Staging system includes:
 - Stage I: tumors within intact cortical bone without clinical expansion
 - Stage II: tumors within intact cortical bone with clinical expansion
 - Stage III: tumors with perforation of cortical bone
- Surgical resection is preferred treatment for CMEC and may include conservative versus aggressive surgical intervention:
 - Conservative surgery includes curettage, enucleation, or marsupialization:
 - Recurrence rates of up to 40%
 - Aggressive surgery includes segmental resection:
 - Recurrence rates of approximately 13%
- Metastatic disease occurs in less than 10% of cases.

Treatment and Prognosis

- Marginal resection is recommended:
 - Enucleation or curettage not advocated owing to associated high recurrence rates (>50%)
- Long-term follow-up recommended

ODONTOGENIC NONDEVELOPMENTAL CYSTS

Radicular or Periapical Cyst (Figs. 5-8 through 5-9)

Definition: Inflammatory odontogenic epithelial-lined cyst arising from epithelial odontogenic rests (rests of Malassez) in the periodontal ligament secondary to inflammation following necrosis of the dental pulp:

Fig. 5-8. Radicular cyst: imaging findings.

Radicular cyst in the maxilla of right lateral incisor tooth. Periapical image shows a well-defined unilocular radiolucency (arrows), around the apex of the upper right lateral incisor tooth. Note the continuity between the cystic lesion and the periodontal ligament space of the affected tooth (arrowhead). (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 25-8, p 1476.)

- In many instances, true epithelial-lined cysts do not develop and tissue represents inflamed connective tissue referred to as periapical granuloma:
 - Not true granuloma
 - Also referred to as chronic apical periodontitis
 - Represents a mass of granulation tissue at the apex of a nonvital tooth resulting from escape of inflammatory cells and bacterial products from a necrotic pulp usually caused by dental caries
 - Periapical granulomas may develop after resolution of a periapical abscess.

Synonyms: Apical cyst, apical periodontal cyst, dental cyst

Clinical

- Most common cyst of the jaws
- No gender predilection; may occur at any age but most commonly occurs in the third to sixth decades of life
- May affect any tooth but is most commonly identified in association with the anterior maxilla:
 - Invariably associated with nonvital tooth:
 - Associated with teeth that have extensive caries or history of trauma (physical, chemical) resulting in pulpal necrosis
 - Rarely seen in primary dentition
 - Usually associated with apical foramen of nonvital tooth, hence the designation periapical cyst
 - May occur in association with any portion of the tooth, hence the term radicular cyst, which is the preferred terminology
- Most cases are asymptomatic unless there is exacerbation by an acute inflammatory reaction.
- Symptoms associated with the affected tooth include pain during mastication and sensitivity to percussion.
- Multiple cysts may develop in the same patient; no association with any syndromes
- Radiographic features include:
 - Presence of a well-circumscribed, unilocular radiolucency of variable size surrounding the apex of the involved tooth

Pathology

Histology

- Cyst is lined by nonkeratinizing stratified squamous epithelium.
 - In presence of inflammation, the epithelial lining of the cyst may be hyperplastic with acanthosis and spongiosis.
 - A variable number of mucocytes (goblet cells, mucous cell metaplasia) may be identified but are not as common as seen in dentigerous cysts.
 - Intraepithelial linear or arch-shaped calcifications known as Rushton bodies occasionally can be identified:

Fig. 5-9. Radicular cyst.

A, Noninflamed epithelial lined cyst (*arrowhead*) with mural cholesterol granuloma formation. **B**, Higher magnification of the noninflamed epithelial-lined cyst composed of a nonkeratinizing, nonproliferative (hyperplastic)-appearing squamous epithelium (*top*). **C**, Inflamed epithelial lined cyst (*arrowheads*) showing proliferative (hyperplastic) epithelial changes. **D**, Higher magnification shows the proliferative (hyperplastic) appearing squamous epithelium.

- Hyalinized, eosinophilic, angulated, linear, or curved foci within epithelium
- Not specific for radicular cyst as can be seen in dentigerous and other cysts
- Of unknown origin
- Cyst wall consists of dense fibroconnective tissue with an admixed acute and chronic inflammatory cell infiltrate.
- Additional histologic findings that can be found include:
 - Mineralization/dystrophic calcification
 - Cholesterol clefts with multinucleated giant cells (cholesterol granulomas)
 - Hemorrhage (recent and remote in the form of hemosiderin deposition)
 - Hyaline bodies can be found in the cyst wall appearing as small circumscribed pools of eosinophilic material that may be surrounded by an inflammatory cell infiltrate, including neutrophils, lymphocytes, plasma cells, and multinucleated giant cells
- Cyst lumen is filled with fluid and cellular debris.
- Cysts that approximate a paranasal sinus may be lined in part or in total by pseudostratified respiratory epithelium.
- Periapical granuloma:
 - Composed of granulation tissue with associated mixed acute and chronic inflammation surrounded by fibrous connective tissue
 - Among the chronic inflammatory cells seen are mature plasma cells with intracytoplasmic eosinophilic globules representing immunoglobulins (Russell bodies) and foamy (lipid-laden) histiocytes.
 - Scattered epithelial nests (rests of Malassez) may be identified within the granulation tissue.

- Cholesterol granulomas, fresh hemorrhage, and hemosiderin deposition may be present.
- Scattered small foci of neutrophilic accumulation (abscess) may be found but do not reach a level diagnostic for a periapical abscess.
- Periapical abscess represents the accumulation of neutrophils at the apex of a nonvital tooth.

Differential Diagnosis

- Variety of odontogenic and nonodontogenic cysts
- Periapical scar:
 - Area in bone in which a defect is created by periapical inflammatory lesions that is filled in with dense collagenous tissue
 - Features seen in association with a periapical scar that are similar to those of periapical cysts and granulomas include involvement of a nonvital tooth, asymptomatic presentation, and presence of a sharply delineated radiolucency.
 - Histologically, periapical scars consist of collagenous stroma with sparse inflammatory cells.
 - Diagnosis of a periapical scar is suspected in the presence of a history of previous periapical lesion, and radiographic imaging showing evidence of root canal filling.

Treatment and Prognosis

- Treatment includes curettage after extraction of the involved tooth or conservative nonsurgical endodontic therapy with or without extraction of the root apex.
- Recurrence is rare; however, incomplete excision may result in a residual cyst:
 - Designation used for periapical cysts that remain in the jaws after extraction of associated tooth
 - Histologically, may represent area of chronic inflammation or show features of periapical granuloma
- Potential complications may include development of abscess formation, which in turn may progress into an osteomyelitis.
- No known progression to an ameloblastoma

HETEROTOPIAS (CHORISTOMAS) OF THE ORAL CAVITY

Fordyce Granules (Fig. 5-10)

Definition: Collections of sebaceous glands in the oral cavity:

- Because sebaceous glands are not a normal histologic component of the oral cavity mucosa these collections of sebaceous glands are heterotopic.

Fig. 5-10.

A, Oral cavity biopsy in which there were incidentally identified submucosal lobules of unremarkable sebaceous glands (Fordyce granules) with intact overlying stratified squamous epithelium. **B,** Higher magnification showing typical sebaceous cells characterized by multivacuolated cytoplasm and scalloped centrally located nuclei.

Synonyms: Fordyce disease; Fordyce condition; ectopic sebaceous glands; sebaceous hyperplasia

Clinical

- Presence of sebaceous glands within the oral cavity affect from 70% to 95% of the adult population but seldom do these collections coalesce to form a mass lesion.
- No gender predilection; occurs primarily in adults and only rarely identified in children:
 - Paucity in children probably related to the fact that sebaceous glands and hair follicles do not attain maximal development until puberty
- Although any mucosal site of the oral cavity may be affected, most commonly occur on the buccal mucosa, upper and lower lips (inner surface),

retromolar region, tongue, gingival, palate, and tonsillar areas:

- Most commonly seen in a bilateral symmetric distribution on the buccal mucosa opposite the molar teeth
- Other than the oral cavity, head and neck sebaceous gland ectopia may be seen in the parotid gland, larynx, middle ear, and sinonasal region.
- Usually asymptomatic; sometimes create surface roughness
- Appear as raised, yellow- or white-appearing spots or papules with a symmetric distribution measuring 1 to 3 mm in greatest dimension:
 - Uncommonly, coalesce to form large plaques
 - May appear cauliflower-like

Pathology

Gross

- Clinical appearance of Fordyce granules is often diagnostic; these lesions are usually not biopsied.

Histology

- Most often the histologic diagnosis of Fordyce granules is an incidental finding in biopsies of the oral mucosa for other reasons.
- Histologic appearance includes presence of typical sebaceous glands composed of cells with abundant foamy-appearing cytoplasm:
 - Sebaceous glands are present in one or more lobules and are found within the submucosa immediately beneath an intact squamous epithelium.
 - Intact squamous epithelium may be raised owing to the sebaceous gland proliferation.
- In contrast to cutaneous sebaceous glands, those of Fordyce granules are not associated with hair follicles.
- Adjacent stroma is unremarkable except for the possible presence of an inflammatory cell reaction.
- Immunohistochemistry:
 - EMA and cytokeratin positive

Differential Diagnosis

- Coalescence of sebaceous glands into a larger mass may engender the diagnosis of sebaceous gland hyperplasia or sebaceous adenoma:
 - Differentiation of heterotopia versus hyperplasia versus neoplasia is academic because the treatment would essentially be similar.
 - Some authorities advocate that in the setting of a clinically distinct lesion requiring a biopsy for diagnosis and composed of no fewer than 15 normal sebaceous lobules should be diagnosed as sebaceous gland hyperplasia.
- Salivary gland neoplasms with sebaceous cells

Treatment and Prognosis

- No treatment is required.
- Antibiotic therapy may be required for those lesions that become inflamed or infected.
- Very rarely a sebaceous adenoma may develop from these structures.
- Intraoral sebaceous carcinoma presumably originating from Fordyce granules is a rare occurrence (Fig. 5-11):
 - Associated with infiltrative growth
 - May identify presence of pagetoid spread of sebaceous cells within the surface epithelium

Other Oral Choristomas (Fig. 5-12)

- Other choristomas of the oral cavity include the following tissue types:
 - Glial (central nervous system), gastrointestinal, osseous, cartilaginous, or hair follicles
- Uncommon lesions
- More common in women than in men; occur over a wide age from newborns to the eighth decade
- Most common site of occurrence is the tongue
- Present as painless swellings in the oral cavity:
 - Duration of lesions ranges from months to years
 - Appear as nodular, firm mass with normal overlying mucosa
- Glial (central nervous system) heterotopia:
 - Lack connection to the central nervous system.
 - May be composed of astrocytes, oligodendrocytes, ependymal tissue, choroid plexus
 - Immunoreactive for GFAP and S100 protein
- Oral heterotopic gastrointestinal tissue or cyst:
 - Predilection for males; most cases seen by 2 years of age
 - Asymptomatic swelling in floor of mouth
 - Cyst lined by gastric (cardiac, fundic, or pyloric) or intestinal epithelium (e.g., colonic, pancreatic)
 - Stratified squamous or respiratory epithelium may be present.
 - Cyst wall may contain smooth muscle and/or gastric glands.
- For all choristomatous lesions, simple surgical excision is curative.

Ectopic Thyroid Tissue

Definition: Presence of thyroid tissue in abnormal locations.

- Most common in neck in association with the hyoid bone representing thyroglossal duct cyst; for detailed discussion see Section 8.
- Excluding and in comparison to thyroid tissue seen in association with thyroglossal duct cysts, the

Fig. 5-11. Sebaceous carcinoma of the oral cavity.

Intraoral sebaceous carcinoma presumably arising from Fordyce granules. **A**, Lobulated neoplastic proliferation lying contiguous to the surface epithelium. **B**, Lesional cells infiltrate into surface epithelium (pagetoid spread; *arrowheads*). **C**, Lesional (sebaceous) cells characterized by irregular appearing nuclei pleomorphism and abundant vacuolated cytoplasm with distinct scalloping of the nuclei; scattered mitotic figures are seen (*arrow*). **D**, Lesional cells are immunoreactive for epithelial membrane antigen.

Fig. 5-12. Oral heterotopic gastrointestinal tissue.

Oral cavity cyst in which heterotopic gastrointestinal tissue was identified.

presence of ectopic thyroid tissue in other sites is rare and is seen almost exclusively in suprahyoid locations.

- Most common ectopic focus for thyroid tissue is the base of the tongue, where it is referred to as lingual thyroid; however, ectopic thyroid may be seen in any location from the tongue to the supra-sternal notch.

Lingual Thyroid

Definition: Developmental anomaly in which there is abnormal descent of the thyroid gland with localization to the base of tongue.

- For a more complete discussion, including illustrations, see Section 8, Thyroid Gland.

INFECTIOUS DISEASES OF THE ORAL CAVITY

- Infectious diseases of the oral cavity occur in immune-competent and immunocompromised individuals and include a variety of infectious agents, including:
 - Fungal
 - Viral
 - Bacterial and mycobacterial
 - Others

FUNGAL DISEASES

Oral Candidiasis (Fig. 5-13)

Definition: Infection with yeastlike fungal microorganisms *Candida albicans* with diverse clinical presentations and influenced by host immune status.

Synonyms: Moniliasis; candidosis

Fig. 5-13. Oral candidiasis.

A, Oral candidiasis (thrush) in an immunocompromised patient appearing as “cheesy” or creamy-appearing plaques coating the tongue. **B,** Periodic acid Schiff staining highlighting *Candida* spores and hyphae.

Clinical Features

- One of the more common fungal infection in humans and the most common oral fungal infection
- Clinical forms of candidiasis are varied and include:
 - Pseudomembranous candidiasis (also known as thrush):
 - Most common
 - Erythematous candidiasis
 - Chronic hyperplastic candidiasis (also referred to as candidal leukoplakia)
 - Mucocutaneous candidiasis
- Often occurs in setting of immunocompromised and/or debilitated patient:
 - This patient population makes up the largest percentage of patients with oral candidiasis.
- Oral candidiasis also occurs in immune-competent (healthy) patients.
- Staining (10% KOH) and culture (Sabouraud dextrose agar) are methods most commonly used for diagnosing primary candidiasis.

Pseudomembranous Candidiasis or Thrush

- Characterized by presence of white plaques that adhere to the mucosa and give appearance of cottage cheese
- Common sites of occurrence include the buccal mucosa, dorsal tongue, and palate.
- Patients may experience a burning sensation and/or have a foul taste in their mouths.
- Plaques may be removed with exposing an underlying erythematous-appearing mucosa.

Erythematous Candidiasis

- Includes varying clinical presentations
- Early or acute atrophic candidiasis typically follows a course of broad-spectrum antibiotics:
 - Includes diffuse loss of the filiform papillae of the dorsal tongue appearing as patchy, denuded foci; patients complain of a burning sensation.
- Chronic erythematous candidiasis includes:
 - Median rhomboid glossitis (also referred to as central papillary atrophy of the tongue), which was initially considered to be a developmental defect of the tongue
 - Lesions typically asymptomatic, resulting in filiform papillae of the posterior tongue appearing as well-demarcated, erythematous zones seen in the midline, posterior dorsal tongue
 - When these lesions are associated with candidiasis of other oral mucosal sites, it is termed chronic multifocal candidiasis.

- Other sites of involvement may include:
 - Junction of the hard and soft palate
 - Angles of the mouth (angular cheilitis or perlèche)

Chronic Hyperplastic Candidiasis

- Represents mucosal white patch that cannot be rubbed off and is the result of candida infection
- Also referred to as candidal leukoplakia (see later section under inflammatory lesions epithelial lesions):
 - Controversial entity in that a cause and effect (candidal infection producing a leukoplakic lesion) is not universally accepted, and some authorities feel that this process may represent candidal infestation occurring as a secondary process on a preexisting leukoplakic lesion
 - Clinical appearance is that of nondescript leukoplakia typically involving the (anterior) buccal mucosa.
 - Some lesions have admixed red-white lesion referred to as erythroleukoplakia; the latter, in contrast to a purely leukoplakic lesion, is more apt to harbor an underlying significant dysplasia and/or carcinoma.

Mucocutaneous Candidiasis

- Rare acquired or inherited (autosomal recessive) immunologic disorder in which the extent of candida infection is predicated on the extent of the immunologic disorder
- Immunologic dysfunction generally manifests in the first few years of life.
- Intraoral candidal infection manifests as thick, white plaques that do not rub off.

Pathology

Histology

- There are several members of the *Candida* genus, but most common cause of upper aerodigestive tract mucosal candidiasis is *C. albicans*:
 - Dimorphic fungus that includes a yeast form and a hyphal form:
 - Hyphal form is considered responsible for tissue invasion and a diagnosis of candidiasis is based on finding hyphae or pseudohyphae.
 - Hyphae vary in length, are branched, and may be apparent by hematoxylin and eosin staining.
- Histochemistry:
 - Microorganisms may be difficult to identify by conventional staining and in suspected cases special stains, including periodic acid Schiff or Gomori methenamine silver, may be required for definitive identification.
- Microorganisms are typically found in the thickened parakeratin layer and in the superficial spinous layer.

- In conjunction with the fungal infestation there usually is an associated neutrophilic infiltrate that may or may not coalesce to form microabscesses; the neutrophilic cell infiltrate is not a pathognomonic finding, but its presence in the superficial areas should prompt consideration for an infectious cause, specifically fungal infection.
- In addition to the fungal infection and acute inflammatory cell reaction additional findings may include:
 - Hyperkeratosis, parakeratosis, orthokeratosis, irregular epithelial hyperplasia with elongated rete ridges, and a submucosal nonspecific chronic inflammatory cell reaction
 - Reactive basal zone epithelial atypia may be present.
- Less commonly, fungi are present within deeper epithelial layers; the latter is more common in patients with a significant immunocompromised condition.

Differential Diagnosis

- In general, a diagnosis of oral mucosal candidiasis is established on clinical grounds:
 - Biopsy of a given lesion may be required for those lesions that are unresponsive to antifungal therapy or in the setting of chronic hyperplastic candidiasis.
 - Differential diagnosis in the setting of chronic hyperplastic candidiasis may include exclusion of a significant epithelial dysplasia (i.e., moderate or severe dysplasia) and/or squamous cell carcinoma.

Treatment

- Antifungal therapy is preferred treatment:
 - Mainstay for treatment is use of polyenes, such as nystatin and amphotericin B, and azoles including miconazole, fluconazole, and itraconazole:
 - May be used prophylactically during cancer therapy
- Oropharyngeal candidiasis remains a problem in HIV-infected population despite the availability of antiretroviral therapy (ART).
- Topical therapies may provide effective management in noncompromised hosts.

Other Fungi

- Other fungal infections include histoplasmosis, cryptococcosis, mucormycosis, blastomycosis, and aspergillosis.
- More often these fungi infect nonoral mucosal sites or the skin.
- Mucosal infestation may be associated with (florid) pseudoepitheliomatous hyperplasia of the surface epithelium.
- See Section 1, Sinonasal Tract, for a more complete discussion.

VIRAL DISEASES OF THE ORAL CAVITY

- Numerous viral diseases may potentially infect sites in the oral cavity, including:
 - Herpesvirus family characterized by:
 - Double-stranded DNA core surrounded by capsid proteins and ensheathed in an envelope
 - Herpesvirus pathogens include:
 - Herpes simplex viruses (HSV)
 - Varicella-zoster virus (VZV)
 - Cytomegalovirus (CMV)
 - Epstein-Barr virus (EBV)
 - Kaposi sarcoma-associated herpesvirus (KSHV)
 - Human papillomavirus
- Viral infection of the mucosa of the upper aerodigestive tract often occurs in setting of immunocompromised and/or debilitated patient (e.g., organ recipient, immunosuppressive oncologic therapy in cancer patient):
 - Makes up the largest percentage of patients with oral viral diseases
 - Coinfections may occur, including:
 - HSV and CMV
 - EBV and CMV
 - In the above settings *Candida* infestation may also be identified.

Herpes Simplex Virus (HSV)

(Figs. 5-14 and 5-15)

- DNA virus that is trophic to epithelium (epitheliotropic) and nerve ganglia
- Two distinct subtypes of HSV are identified:
 - HSV type 1, referred to as the “oral” type
 - HSV type 2, referred to as the “genital” type
 - Virus type is not necessarily a reliable indicator of anatomic site affected, especially with changing sexual habits.
- Owing to its tendency to infect cells of ectodermal origin (skin or mucous membranes) HSV is a frequent cause of mucocutaneous disease.
- Primary herpetic gingivostomatitis:
 - Acute onset of painful coalescent ulcers on any mucosal surface
 - Frequent on labial mucosa, tongue, and gingiva
 - May be associated with viral prodrome, malaise, and fever
- In healthy patients recrudescence infection includes herpes labialis (fever blisters or cold sores)
- In immune-compromised patients, recrudescence infection may include ulcers anywhere on oral mucosa and appear aphthous-like.

Fig. 5-14. Herpesvirus infection.

Mucocutaneous involvement by herpes simplex virus includes (A) external lip; (B) labial mucous membrane (herpetic stomatitis); (C) herpes zoster infection or dermatomal zoster (shingles).

Fig. 5-15. Herpes simplex virus infection.

A, Histologic findings in herpes simplex virus (HSV) include the presence of intranuclear eosinophilic inclusions (Cowdry cells; *arrowheads*) within degenerating (squamous) epithelial cells imparting a ground glass appearance and multinucleated giant cell (*arrow*) characterized by presence of syncytial cells with intranuclear inclusions and tendency of nuclei to mold to one another. **B**, HSV immunoreactivity (nuclear) and in situ hybridization (nuclear) staining confirm the diagnosis.

Pathology

Gross

- Single or multiple, oval, tan-white, ulcerated lesions with a hyperemic rim with or without an associated exudate

Histology

- Ulceration with associated acute and chronic inflammation:
 - Intraepithelial vesicle formation marked by acantholysis and balloon degeneration of epithelial cells
 - Intranuclear eosinophilic inclusions (Cowdry cells) may be identified within the degenerating epithelial cells, imparting ground glass appearance
 - Multinucleated giant cells may be numerous, identified along edge of the ulcer, and characterized by:
 - Syncytial cells with intranuclear inclusions
 - Tendency of nuclei to mold to one another
- Special stains:
 - Immunoreactivity for HSV-1 and/or HSV-2 (nuclear staining)
 - In situ hybridization positive in infected cells (nuclear staining)

Differential Diagnosis

- Herpes zoster infection:
 - Part of varicella zoster virus, the agent for chickenpox and herpes zoster infections
 - May occur as varicella (chickenpox) or as dermatomal zoster (shingles):
 - Zoster may represent an early marker for the immunosuppression associated with HIV infection but is not specific for HIV infection.
 - Can localize to any dermatome, is neurotropic, and can cause unremitting pain
 - Infection may appear as vesicular lesions that bleed easily and may be covered with a black crust or as shallow tonsillar ulcers covered with a gray exudates; histologic findings may overlap with those of HSV, so immunostains and in situ hybridization are required for accurate diagnosis.
 - Head and neck manifestations include involvement of the eighth nerve or geniculate ganglion (Ramsay Hunt syndrome), producing severe ear pain, hearing loss, vertigo, and facial nerve paralysis.
 - Intranuclear inclusions indistinguishable from those seen in herpes simplex are identified.
- Cytomegalovirus

Treatment

- Antiviral chemotherapy including acyclovir, ganciclovir, and foscarnet

Cytomegalovirus (CMV)

(Fig. 5-16)

- In general, CMV infection involving the head and neck is not common, when it occurs in the head and neck usually occurs in immunocompromised and/or debilitated patient or organ transplant recipients:
 - Most common opportunistic pathogen recognized at autopsy in AIDS patients
- Appears as an ulcerative mucocutaneous lesion

Pathology

Gross

- Single or multiple, oval, tan-white, ulcerated lesions with a hyperemic rim with or without an associated exudate

Histology

- Mucosal ulceration, necrosis, and cytomegaly, the latter including:
 - Epithelial and/or mesenchymal (e.g., endothelial) cells with enlarged nuclei and prominent red nucleoli (“owl-eye”) and dark pink intracytoplasmic granules
- Special stains:
 - Immunoreactivity for CMV (nuclear and/or cytoplasmic)

Fig. 5-16. Oral mucosal cytomegalovirus infection.

A, Cytomegalovirus (CMV) lesions on palate characterized by multiple, discrete, oval mucosal lesions. **B**, Histologic findings include cytomegaly with enlarged nuclei and prominent red nucleoli (*arrowhead*) and dark pink intracytoplasmic granules (*arrow*). **C**, CMV immunoreactivity and (**D**) in situ hybridization staining (nuclear and/or cytoplasmic) confirms the diagnosis. Infected cells may include epithelial and/or mesenchymal (e.g., endothelial) cells.

- In situ hybridization positive in infected cells (nuclear and/or cytoplasmic)

Treatment and Prognosis

- Antiviral therapy with ganciclovir and valganciclovir

Epstein-Barr Virus (EBV)

- Epstein-Barr virus (EBV) is an enveloped icosahedral herpesvirus with double-stranded linear DNA.
- EBV is strongly tropic for B-lymphocytes and also tropic for T-lymphocytes.
- Oral manifestations of EBV infection include oral hairy leukoplakia; see later in this section.
- For more complete discussion on EBV-related diseases, see Section 3, Pharynx.

Kaposi Sarcoma–Associated Herpesvirus (KSHV)

- Large, enveloped, double-stranded DNA virus
- Represents eighth human herpesvirus, hence the designation as human herpesvirus-8 (HHV-8):
 - HHV-8 is presumed causative agent of Kaposi sarcoma (KS)
- HHV-8 infects endothelial cells as well as peripheral blood monocytes and B lymphocytes in patients with KS.
- Latency-associated nuclear antigen (LANA-1) is KSHV latent protein:
 - LANA expressed during latent HHV-8 infection:
 - Expression (nuclear staining) by immunohistochemical staining found in all cases of KS
 - Expression not reported in non-KS neoplasms except for primary effusion lymphoma and Castleman disease
- For more complete discussion of Kaposi sarcoma and HHV-8, see later in this section.

Human Papillomavirus (HPV)

- HPV represents a large group of small, double-stranded circular DNA viruses.
- HPV is strongly epitheliotropic.
- HPV is a sexually transmitted disease.
- Non-neoplastic oral diseases associated with HPV include (but are not limited to):
 - Verrucae (verruca vulgaris [wart], condyloma acuminatum)

Fig. 5-17. Actinomycotic infestation of bone.

Actinomycotic infestation of the mandible in a patient with a history of squamous cell carcinoma and postoperative radiotherapy. The microorganisms appear light blue (arrow) with associated neutrophilic infiltrate involving necrotic bone.

- Heck disease (also known as focal epithelial hyperplasia); see later in this section
- HPV is also associated with oral epithelial neoplasms, including squamous papilloma.
- For a more complete discussion see Section 3, Pharynx, and Section 4, Neck.

BACTERIAL DISEASES

Bacteria and Spirochetes

- Oral bacterial diseases may include gonorrhea and syphilis:
 - May occur in immunocompromised or in immune-competent (healthy) individuals
- For detailed discussion see Section 3, Pharynx.
- Actinomycotic colonies may infect bone, especially secondary to invasive squamous cell carcinoma (Fig. 5-17).
 - For more complete discussion of actinomycosis see Section 4, Neck.

Mycobacterial Infections

- See Section 4, Neck, for detailed discussion including illustrations.

REACTIVE, INFLAMMATORY, AND TUMOR-LIKE LESIONS OF THE ORAL CAVITY

ORAL HPV-ASSOCIATED EPITHELIAL LESIONS

- HPV is epitheliotropic, infecting stratified squamous cutaneous and mucosal epithelial cells.
- Benign HPV-associated oral epithelial lesions include:
 - Oral verruca vulgaris (common wart)
 - Oral condyloma acuminatum
 - Focal epithelial hyperplasia (Heck disease)
 - Oral squamous papilloma
- May share similar clinical presentations and histologic features

Verruca Vulgaris (VV) of the Oral Mucosa (Fig. 5-18)

Definition: Benign squamous epithelial proliferation related to human papillomavirus (HPV).

Synonym: Wart

Clinical

- More common in men than in women; occurs over a wide age range but most common in the third and fourth decades of life:
 - Can also be seen in children

Fig. 5-18. Oral verruca vulgaris.

A, At low magnification characterized by an exophytic papillomatous epithelial proliferation with prominent hyperkeratosis, including thickened external orthokeratosis, acanthosis, and elongated rete ridges; characteristically rete ridges along the periphery show angulation toward the center of the lesion. **B**, Prominent granular cells and koilocytes are present in the more superficial aspect of the proliferation. **C**, HPV 6/11 immunoreactivity.

- Most common sites of occurrence include the lips, palate (hard and soft), and tongue, but any oral mucosal site can be affected.
- Presents as a circumscribed, exophytic white lesion with firm consistency and a papillary appearance protruding from mucosal surface
- Most often a single lesion but multiple lesions may occur
- Caused by HPV types 2 and 4 and less often by types 6, 11, and 16:
 - Route of infection is thought to be by autoinoculation, possibly from the hands from a cutaneous lesion

Pathology

Gross

- Firm, white, sessile, exophytic growth with a papillomatous appearance

Histology

- Histology of oral mucosal VV is the same as the more common cutaneous VV:
 - Characterized by a exophytic papillomatous epithelial proliferation with prominent hyperkeratosis, including thickened external orthokeratosis, acanthosis, and elongated rete ridges:
 - Characteristically rete ridges along the periphery showing angulation toward the center of the lesion
 - Base of the lesion can be sessile or pedunculated.
- Epithelium is cytologically bland, has a prominent granular layer, and koilocytes seen in the majority of cases localized to more superficial aspects:
 - Koilocytes characterized by presence of hyperchromatic, pyknotic (“raisinoid”)-appearing nuclei surrounded by clear cytoplasm
- Mixed chronic inflammatory cell infiltrate may or may not be present in the subjacent stroma.
- No evidence of epithelial dysplasia
- Special studies:
 - Although unnecessary for the diagnosis, presence of HPV can be detected by immunohistochemical, electron microscopic, and molecular diagnostic (in situ hybridization and polymerase chain reaction) studies.

Differential Diagnosis

- Oral squamous papilloma:
 - Also may be associated with HPV
 - From a histologic standpoint, in contrast to verrucae, papillomas typically lack surface keratinization, a prominent granular cell layer, koilocytes, and angulation of the rete ridges at the periphery toward the center of the lesion.
- Condyloma acuminatum

Treatment and Prognosis

- Removal of the lesion is the preferred treatment and can be performed by surgery, cryosurgery, or electrosurgery.
- Recurrences are rare.
- Spontaneous regression/disappearance within 1 to 2 years may occur, especially in children.

Condyloma Acuminatum

Definition: Sexually transmitted, benign papillomatous epithelial proliferation due to HPV.

- Derived from the Greek words *kondylos* (knob or knuckle) and *acumen* (point)

Synonyms: Venereal wart; venereal condyloma

Clinical

- Because condyloma acuminatum is a sexually transmitted disease, it is more apt to develop in areas of sexual contact such as the anogenital region.

Oral Mucosal Condyloma Acuminatum (Fig. 5-19)

- No gender predilection and can be seen in all ages but tends to be most common in teenagers and young adults
- Most common oral mucosal sites of occurrence include the tongue (dorsum), lips (upper and lower), lingual frenum, and soft palate/uvula
- Often asymptomatic
- Solitary (condyloma acuminatum) or multiple (condyloma acuminata) sessile to papillary mucosal-based lesions
- Immunocompromised individuals (e.g., HIV-infected, organ transplant recipients) at increased risk for oral condylomas
- Associated with HPV types 6 and 11 in the majority of oral lesions; HPV types 16 and 18 are present in a minority of cases:
 - Condyloma is very contagious.
 - Primary sexual transmission after direct contact is the principal mode of transmission.
 - Less often, transmission may occur via hematogenous spread, autoinoculation from anogenital lesions, or perinatal transmission from mother to infant.

Pathology

Gross

- Solitary or multiple, broad-based sessile mass with a papillary, cauliflower-like, mulberry growth, reddish-pink appearance
- Tend to be larger than papillomas, usually measuring 1.0 to 1.5 cm but may reach up to 3 cm in greatest dimension

Fig. 5-19. Oral condyloma acuminatum.

A, Broad papillary epithelial fronds with prominent acanthosis. **B**, Koilocytotic cells characterized by hyperchromatic, pyknotic nuclei surrounded by clear zone. **C**, Rounded rete ridges, scattered mitotic figures, and dilated capillaries with mixed chronic inflammatory cell reaction in the submucosa.

Histology

- Broad papillary epithelial fronds with prominent acanthosis, parakeratin crypt formation, and koilocytosis (hyperchromatic, pyknotic nuclei surrounded by clear zone)
- Rete ridges appear bulbous in their depth.
- Numerous mitotic figures can be seen.
- Subjacent stroma shows dilated capillaries and variable mixed chronic inflammatory cell reaction, including mature lymphocytes and plasma cells.
- May involve excretory ducts of minor salivary glands
- Special studies
 - Although unnecessary for the diagnosis, the presence of HPV can be detected by immunohistochemical, electron microscopic, and molecular diagnostic (in situ hybridization and polymerase chain reaction) studies.

Differential Diagnosis

- Squamous papilloma
 - Presence of marked acanthosis, parakeratin crypt formation, numerous koilocytes, and sessile appearance of condyloma acuminatum assists in differentiating it from squamous papilloma.
- Verruca vulgaris
 - Condyloma acuminatum and verruca vulgaris have overlapping histologic features; however, differences include:
 - Presence of marked hyperorthokeratinization and angulated rete ridges along the periphery toward the center of the lesion in verruca vulgaris
 - Condyloma acuminata show more extensive acanthosis as well as the more consistent presence of stromal dilated capillaries and

superficial mixed chronic inflammatory cell infiltrate.

Treatment and Prognosis

- Removal of the lesion is the preferred treatment and can be performed by surgery, cryosurgery, or electrocautery.
- Recurrences are common.
- Spontaneous regression/disappearance may occur.
- Unlike uterine cervical HPV-associated lesions, in which HPV association is considered precancerous, the same precancerous nature is not felt to be true relative to oral mucosal lesions.

Focal Epithelial Hyperplasia (FEH)

(Fig. 5-20)

Definition: Benign oral mucosal epithelial proliferation caused by HPV.

Synonym: Heck disease

Clinical

- Uncommon lesion
- No gender predilection; initially identified in children but affects all age groups
- Propensity to affect specific ethnic groups, including:
 - Native American Indians, Central and South American Indians, Eskimos
- Limited to the oral cavity and most commonly found:
 - Lower and upper lip, buccal mucosa, tongue
- Clinically, typically characterized by multiple, painless, soft, sessile papules, plaques, or nodules, which may coalesce to give rise to larger lesions
- Cause:
 - HPV types 13 and 32 detected in majority of lesions
 - Other subtypes may be identified, including HPV-6 and HPV-11
 - Rarely associated with high-risk HPV (HPV-16)
- Considered to potentially represent an oral manifestation of AIDS

Pathology

Gross

- Soft, tan-pink appearing lesions measuring from 0.1 to 1 cm in greatest dimension

Histology

- Irregular epithelial hyperplasia with hyperkeratosis, parakeratosis, and acanthosis
- Rete ridges are widened and may be fused or appear confluent:
 - Elongation of the rete ridges not usually seen
- Thickened epithelial proliferation extends in an exophytic rather than endophytic manner, resulting in

Fig. 5-20. Focal epithelial hyperplasia (Heck disease).

A, Irregular epithelial hyperplasia with hyperkeratosis, parakeratosis, and acanthosis; the lesion has an endophytic growth with widened and fused rete ridges. **B**, A characteristic feature is the presence of mitosoid cells characterized by cells with collapsed nuclei that take on the appearance of a mitotic figure.

rete ridges in the lesion at the same level or depth as adjacent nonlesional epithelial rete ridges.

- Koilocytes can be seen in cells of superficial keratinocytes.
- Mitosoid cells or bodies characterized by the presence of cells with collapsed nuclei taking on the appearance of a mitotic figure can be seen.
- Immunohistochemistry:
 - Identification of HPV-13 and HPV-32
- Electron microscopy:
 - Virus-like particles can be found by ultrastructural analysis in the nuclei and cytoplasm of cells within spinous layer.

- Cytogenetics and molecular genetics:
 - Presence of HPV-13 and HPV-32 identified by in situ hybridization

Differential Diagnosis

- Squamous papilloma
- Verruca vulgaris
- Condyloma acuminatum
- Pseudoepitheliomatous hyperplasia
- Proliferative verrucoid leukoplakia

NOTE: The absence of prominent surface projections, absence of endophytic growth, and presence of mitosoid cells assist in differentiating FEH from these other lesions.

Treatment and Prognosis

- Because these lesions tend to undergo spontaneous regression usually in months (but may take up to a year or more), there is no specific treatment required.
- Some lesions may persist for years.
- Several treatment modalities such as surgical excision, laser ablation, cryotherapy, electrocauterization, topical, intralesional, systemic interferon, and systemic retinoic acid have been used with inconsistent results and many side effects.
- Imiquimod cream has been used with some success for vermilion lesions.
- Transformation to carcinoma does not occur.

ORAL EBV-ASSOCIATED EPITHELIAL LESIONS

Oral Hairy Leukoplakia (OHL)

(Figs. 5-21 and 5-22)

Definition: EBV-induced verruciform hyperkeratotic lesion of the lateral tongue in HIV-infected patients.

Clinical Features

- Affects HIV-infected men more often than HIV-infected women
- Most HIV-infected individuals do not have AIDS at time of diagnosis of OHL but may develop AIDS later in a high percentage of cases:
 - Low CD4 counts
- May occur in non-HIV-positive but immunocompromised patients, including:
 - Organ transplant recipients on immunosuppressive therapy
 - Cancer patients on immunosuppressive oncologic therapies
 - Patients on high-dose corticosteroid treatment
 - Reported as early indicator of EBV-associated posttransplant proliferative disorder
 - Rarely may occur as presenting sign of acute leukemia

Fig. 5-21. Oral hairy leukoplakia.

Oral hairy leukoplakia characterized by the presence of demarcated white plaque to raised, white lesions with vertical corrugations on the lateral aspect of the tongue in a patient with HIV infection.

- Asymptomatic unless secondarily infected (e.g., by *Candida albicans*):
 - OHL often occurs in association with oral cavity *Candida* infestation.
- Lesions typically localize to the lateral tongue but occasionally may involve the ventral or dorsal tongue and infrequently involve other oral sites such as the buccal mucosa.
- White, painless, linear, or plaquelike lesion with white lines running perpendicular to long axis of tongue
- Pathogenesis:
 - Caused by EBV
 - Due to its association with AIDS, OHL was thought to be caused by a variety of microorganisms, including HIV, EBV, human papillomavirus (HPV), and herpes simplex virus (HSV)

Pathology

Gross

- Varies in appearance from a well-demarcated flat, white plaque to a well-demarcated raised, white lesion with vertical striations or corrugations

Histology

- Irregular epithelial hyperplasia characterized by filiform or hairlike keratin projections with associated parakeratosis and acanthosis
- Balloon degeneration of edema may be seen within the deep epithelial layer.
- Koilocytes and cells with Cowdry inclusions (ground glass appearance and intranuclear inclusions) may be seen in superficial epithelial cells lying beneath the parakeratotic layer.

Fig. 5-22. Oral hairy leukoplakia.

A, Oral mucosa in (oral) hairy leukoplakia shows irregular epithelial hyperplasia, band of pale ballooned cells with filiform or hairlike keratin projections associated with parakeratosis and acanthosis. **B,** Cells with perinuclear halos (koilocytes) are identified.

- Absence of intraepithelial dysplasia
- A nonspecific mild chronic inflammatory cell reaction may be seen within the submucosa.
- Exfoliative cytologic examination may prove a useful, simple, cost-effective, and reliable method to diagnose OHL.
- Concomitant fungal (*C. albicans*) microorganisms (spores or hyphae) may be present within the superficial keratin layer:
 - Present in as many as 50% of cases
 - Can be seen by light microscopy and/or by histochemical staining (e.g., GMS, PAS)
- In situ hybridization for Epstein-Barr–encoded RNA (EBER):
 - Used for confirmation of EBV
 - Can be performed on exfoliative cytology material

Differential Diagnosis

- Other oral leukoplakic lesions
- Hairy tongue:
 - Benign condition characterized by hyperkeratosis and enlargement of filiform papillae (see later in this section under oral malignant mucosal melanoma for more detailed discussion)
 - In contrast to OHL, hairy tongue is a poorly demarcated lesion with diffuse involvement of the dorsum of the tongue.
- Verrucous carcinoma:
 - Verrucous carcinoma includes the presence of tiered keratosis and elongated bulbous-appearing rete ridges, features not seen in OHL.

Treatment and Prognosis

- Self-limiting disease and in most cases requires no treatment
- No malignant potential
- Symptomatic lesions usually caused by secondary *Candida* infection require appropriate treatment.
- In HIV/AIDS patients or patients on immunosuppressive therapy, adjustment of antiretroviral and immunosuppressive therapy, respectively, may resolve lesions.
- Owing to its association with HIV, morbidity and mortality may be associated with HIV-associated or AIDS-associated opportunistic infections:
 - Appropriate antibiotic or antiviral therapy may be required.

NONINFECTIOUS BENIGN EPITHELIAL LESIONS

Pseudoepitheliomatous Hyperplasia (PEH) (Fig. 5-23)

Definition: Exuberant reactive or reparative overgrowth of squamous epithelium displaying no cytologic evidence of malignancy that may be mistaken (clinically and histologically) for a squamous cell carcinoma.

Clinical

- Not a distinct clinicopathologic entity; rather it represents a morphologic entity:
 - Wide spectrum in demographics and the clinical presentation
 - May occur as an isolated process or more often is the morphologic process associated with or induced by other diseases or lesions, including:
 - Trauma, chronic denture irritation, tattoo (cutaneous lesions), infections (e.g., due to candida, leprosy, blastomycosis, histoplasmosis, paracoccidioidomycosis, others), and tumors:

Fig. 5-23. Granular cell tumor with pseudoepitheliomatous hyperplasia.

Pseudoepitheliomatous hyperplasia (PEH) of the oral cavity mucosa secondary to granular cell tumor. **A**, Florid epithelial proliferation with hyperkeratosis, acanthosis, and elongation and downward extension of the rete ridges. **B**, Higher magnification shows rete ridges with rounded or smooth contours and bland cytomorphic features intermixed with the cells of the granular cell tumor. **C**, In other areas the rete ridges have an angulated and irregular appearance with dyskeratotic cells that would raise concern for invasive squamous cell carcinoma, but the granular cell proliferation is seen in and around, as well as deep to the epithelial proliferation. **D**, Diffuse and strong S100 protein immunoreactivity in the granular cell tumor. As long as the granular cells lie deep to the squamous epithelial proliferation without squamous cell nests lying deep to the granular cells, the epithelial proliferation should not be considered as being malignant. The exception to the prior statement would be if metastatic disease was present; then the epithelial proliferation even in conjunction with a granular cell tumor would be considered as carcinoma.

- Classically, PEH has been associated with an underlying granular cell tumor (see later in this section).

Pathology

- Characterized by a florid epithelial proliferation with or without associated hyperkeratosis
- Acanthosis with elongation and downward extension of the rete ridges
 - Rete ridges typically have a rounded or smooth-edged appearance but may be angulated and irregular in appearance.
- In general there is an absence of any significant intraepithelial dysplasia:
 - In association with a granular cell tumor, epithelial dysplasia even reaching more severe degrees may be present.
 - In addition, nests of squamous epithelium may take on a more angulated appearance and simulate an invasive growth pattern that approaches (or even reaches) the morphologic level of squamous cell carcinoma (see later in section).
- Histochemistry:
 - If an infectious cause is suspected, then special stains for microorganisms, in particular for fungi (e.g., Gomori methenamine silver, periodic acid Schiff, others), may be required for the diagnosis.
 - Fungal infestation includes presence of fungal forms (hyphae and/or spores) within the depth of epithelium.
 - Fungal forms limited to the surface keratin and/or superficial epithelium are considered colonization and not infestation.

Differential Diagnosis

- In the majority of cases differentiating PEH from a carcinoma is not problematic given the presence of a bland epithelial proliferation with rounded rete ridges and absence of dysplasia.
- As previously noted in association with granular cell tumor morphologic features virtually identical to squamous cell carcinoma may be present, creating difficulties in differentiating PEH from squamous cell carcinoma:
 - Features that assist in differentiating PEH from squamous cell carcinoma include:
 - In association with a granular cell tumor, nests of PEH should not extend below the depth of the granular cell tumor.
 - S100 protein staining may be required to determine the extent of the PEH (S100 protein negative) relative to the granular cell tumor (S100 protein positive)
 - If PEH does not extend below the deepest part of the granular cell tumor, then the squamous

proliferation should not be considered malignant.

- If the epithelial proliferation does extend below the deepest part of the granular cell tumor and/or there is definitive evidence (i.e., histologic confirmation) of metastatic squamous cell carcinoma (e.g., to cervical lymph node, other sites), then presuming there is no previous history or concurrent presence of another primary mucosal squamous cell carcinoma, a diagnosis of squamous cell carcinoma can be rendered in association with a granular cell tumor.
- More recently, distinctive gene expression profiles identified in squamous cell carcinoma and absent in PEH may offer ability to use DNA microarrays to differentiate these lesions.

Treatment and Prognosis

- There is no specific treatment for PEH:
 - If it is occurring in association with or induced by another disease, then therapy should be oriented to treating the other process, for example:
 - Antifungal therapy in presence of fungal infestation
 - Surgery for a granular cell tumor

Necrotizing Sialometaplasia (Fig. 5-24)

Definition: Benign, self-healing (reactive) inflammatory process of salivary gland tissue, which clinically and histologically mimics a malignant neoplasm.

- See Section 6, Salivary Glands, for a more complete discussion.
- Most commonly involves the minor salivary glands of the palate, but other intraoral sites as well as the minor salivary glands of virtually every site in the upper aerodigestive tract can be affected; major salivary gland involvement occurs as well.
- Most common presenting problem is that of a painless ulcerated lesion or a nodular swelling, which is usually unilateral but may be bilateral; in general, the lesions are asymptomatic but may be associated with pain, numbness, or a burning sensation.
- Palatal-based lesions occur spontaneously and are of unknown causes; the majority of cases involving extrapalatal minor salivary glands and major salivary glands are iatrogenically induced after operative procedures, trauma, or radiotherapy with a mean duration of 18 days from the insult to the development of the lesion.
- Pathogenesis for the iatrogenically induced lesions is primarily but not exclusively thought to be ischemic;

Fig. 5-24. Necrotizing sialometaplasia of the palate.

A, At low magnification the lobular architecture of the minor salivary glands within the submucosa is maintained (*arrows*). **B**, Metaplastic lobules vary slightly to moderately in size and shape, and have smooth contours surrounded by reactive stroma; the lobules in the lower portion of the image show prominent keratinization. **C**, Metaplastic lobule with associated keratinization and identification of residual mucous cells (*arrowheads*). **D**, Necrotic lobules consisting of acinus-sized pools of mucin may or may not be present in any given case.

a similar pathogenesis is implicated for the palate lesions; however, this remains unproven.

- Typical appearance is that of a deep, crater-like ulcerative lesion measuring from 1 to 3 cm; however, the lesion may appear as a submucosal nodular swelling that may slough, leaving a crater-like ulcer.

- Histologically, lobular necrosis of the salivary glands with preservation of the lobular architecture and squamous metaplasia of residual acinar and ductal elements are the histologic hallmarks:
 - Necrotic lobules consist of acinus-sized pools of mucin that may extend into adjacent tissue, eliciting a granulation tissue reaction with associated

acute and chronic inflammation (neutrophils and foamy histiocytes).

- Squamous metaplasia is bland in appearance and composed of squamous cells with uniform nuclei and abundant eosinophilic cytoplasm with occasional preservation of ductal lumina and/or scattered mucous cells.
- Lobular architecture is maintained and the metaplastic lobules vary slightly to moderately in size and shape and have smooth edges surrounded by granulation tissue and an intense mixed acute and chronic inflammatory reaction
- With regeneration, mitoses, individual cell necrosis, enlarged nuclei, and prominent nucleoli can be seen; occasionally, the metaplastic cells have a predominantly basaloid appearance with hyperchromatic nuclei.
- Associated findings may include:
 - Ulcerated mucosa
 - Pseudoepitheliomatous hyperplasia resulting when the metaplastic lobules present in excretory ducts and merges with surface epithelium may be so striking presenting a diagnostic nightmare in separation from an infiltrating squamous cell carcinoma.
- These lesions are self-limiting and heal by secondary intention; depending on the size of the lesion, the healing process in most cases occurs from 3 to 12 weeks; debridement and saline rinses may aid in the healing process.
- Recurrences do not usually occur.

MESENCHYMAL LESIONS

Irritation Fibroma (Fig. 5-25)

Definition: Reactive proliferation of submucosal fibrous tissue covered by benign epithelium.

Synonyms: Traumatic fibroma, focal fibrous hyperplasia, fibrous nodule, fibrous epulis, fibroepithelial polyp

Clinical

- Considered the most common soft tissue lesion of the oral cavity
- Female predilection; majority are found in adults between 20 and 59 years of age:
 - May be seen in children, but less commonly
- Most common location is the buccal mucosa adjacent to crowns of teeth (bite line) followed by the gingiva, lips, and tongue
- Presentation is usually that of slow-growing, non-tender gingival swelling:
 - Duration of the lesion varies considerably, but may range up to 17 months

- Usually solitary; rarely may be bilateral, symmetric lesions

- Periapical radiographs show no evidence of osseous pathology.
- Cause:
 - Major cause is mechanical irritation secondary to trauma/injury from dentures, lip or cheek biting, or sharp edges of teeth or fillings
 - Some lesions occur in the absence of a history of trauma or injury, raising the possibility that these lesions are true neoplasms.

Epulis Fissuratum

- Use of the term *epulis* refers to any mass on the gingiva.
- Unique variant of denture-related fibroma typically occurring in the mucosal vestibule or sulcus adjacent to the alveolar ridge, areas where the edge of an ill-fitting denture may traumatize adjacent tissue:
 - Represents a redundant fold of tissue running parallel to the edge of the denture

Retrocuspid Papule

- Another fibrous oral mass occurring as an asymptomatic, firm papule on the lingual aspect of the mandibular cuspid, either on the gingiva or on the adjacent oral mucosa.

Pathology

Gross

- Well-demarcated, firm, dome-shaped nodule with sessile or pedunculated base and a smooth, dome-shaped elevation varying in size from less than 0.5 to 2.0 cm in greatest dimension, but usually measures from 0.5 to 1.0 cm

Histology

- Bland, nodular submucosal proliferation of fibrous connective tissue with overlying intact but attenuated stratified squamous epithelium:
 - Periphery of lesion is not encapsulated and blends imperceptibly into the surrounding connective tissue.
 - Fibrous tissue ranges from dense and coarse (fibroma durum) to delicate and fibrillar (fibroma molle).
 - Proportion of ground substance varies from sparse to abundant.
 - Surface may be ulcerated.
- Fibroblasts are spindle shaped to stellate with inconspicuous, cigar-shaped nuclei evenly distributed throughout the lesion; cytoplasmic borders are not prominent.
- Collagen may be:
 - Arrayed as interlacing, haphazard, or parallel bundles

Fig. 5-25. Irritation fibroma.

A, Right buccal mucosa fibroma appearing as a mucosal covered oval to round bulge. **B**, Cut section of the excised lesion shows a white-appearing lesion. **C**, Bland, nodular submucosal proliferation of fibrous connective tissue with overlying intact stratified squamous epithelium. **D**, Submucosal dense collagen with scattered blood vessels.

- Dense, hyalinized bands (keloidal collagen)
- Loose appearing
- Mitoses are not seen.
- Submucosal mild chronic inflammation and edematous change may be present; limited vascularity is present and any given lesion may be avascular.
- Histochemistry:
 - Connective tissue component is a mixture of glycoproteins and fibers, but the pattern of staining does not differentiate between lesions.

Epulis Fissuratum

- Histologically similar to an irritation fibroma except that there is often a denser chronic inflammatory cell reaction and greater tendency for the surface epithelium to be ulcerated

Retrocuspid Papule

- Histology is similar to the giant cell fibroma (see below), except that in occasional cases rests of odontogenic epithelium can be identified.

Differential Diagnosis

- Keloid
- Fibromatosis
- Giant cell fibroma
- Desmoplastic fibroblastoma (collagenous fibroma):
 - Uncommon benign soft tissue lesion with wide anatomic distribution rarely occurring in oral cavity
 - Paucicellular lesion with abundant collagenous or myxocollagenous matrix, low vascularity, and

scattered bland-appearing stellate- and spindle-shaped fibroblastic cells

- Characteristic cytogenetic abnormalities of chromosome 11q12 with presence of identical t(2;11)(q31;q12) translocation

Treatment and Prognosis

- Surgical excision of the lesion, in conjunction with removal of any apparent source of chronic irritation, is the preferred treatment.
- Recurrence of fibroma is uncommon.

Giant Cell Fibroma (Fig. 5-26)

Definition: Benign submucosal fibrous tumor of the oral cavity characterized by large mononuclear and multinucleated giant cells.

Clinical

- No gender predilection; primarily occurs in the first three decades of life with a peak occurrence in the second decade, although a broad age range has been reported
- Most common location is the gingiva, followed by the tongue, palate, buccal mucosa, and lips
- Periapical radiographs show no evidence of osseous pathology.
- Does not appear to be associated with trauma:
 - Some authorities believe giant cell fibroma should not be separated from irritation fibroma.
 - Absence of associated trauma in giant cell fibroma would support separating it from irritation fibroma
 - Differences in demographics, site of location, and histology also support separating these entities.

Fig. 5-26. Giant cell fibroma of the oral cavity.

Submucosal fibroblasts include scattered stellate to multinucleated giant fibroblasts in a collagenized stroma; separation artifact is focally seen around the fibroblastic cells.

Pathology

Gross

- Mucosal-covered, nodular, pedunculated, or sessile mass often with a papillary appearance and usually measuring less than 1.0 cm in greatest dimension and often less than 0.5 cm.

Histology

- Bosselated nodule of loose fibrovascular connective tissue composed of fibroblasts and collagenized stroma:
 - Fibroblasts include large, stellate-shaped nuclei, as well as numerous multinucleated giant fibroblasts that can be seen scattered throughout the lesion.
 - Collagen may have a whorled pattern and may range from compact to loose in appearance.
 - Separation artifact is sometimes noted around the stellate cells.
- Vascularity and chronic inflammation varies but may be prominently seen in any given case.
- Surface epithelium remains intact, composed of stratified squamous epithelium; prominent, elongated rete ridges may be present.
- Foci of melanin granules may be seen within the giant cells.
- Mitoses are not seen.
- Electron microscopy:
 - Mononuclear and multinuclear cell cytoplasm contains varying numbers of microfibrils in a perinuclear distribution:
 - Microfibrils are predominantly 50 to 100 angstroms in diameter, with a smaller number of fibrils about 125 angstroms in diameter.
 - Amount of rough endoplasmic reticulum supports a fibroblast-like differentiation.

Differential Diagnosis

- Conventional fibroma
- Peripheral giant cell fibroma:
 - Giant cells of giant cell fibroma are not the “osteoclastic”-type giant cells seen in peripheral giant cell fibroma, and the stroma is not as vascular in giant cell fibroma as it is in peripheral giant cell granuloma.

Treatment and Prognosis

- Simple surgical excision is the preferred treatment; recurrence is uncommon.

Oral Fibrosing Lesions

- Two oral fibrosing lesions include oral submucous fibrosis and gingival fibromatosis.

Fig. 5-27. Oral submucous fibrosis.

Oral submucous fibrosis characterized by submucosal hyalinization with replacement of the submucosal soft tissues. The overlying epithelium in this example is essentially unremarkable, although in other examples it may be atrophic and/or show the presence of intraepithelial dysplasia.

Oral Submucous Fibrosis (Fig. 5-27)

Definition: Unique chronic progressive and irreversible generalized fibrosis of oral and oropharyngeal soft tissues characterized by subepithelial fibrosis.

- Associated with chewing areca nut (betel quid), a habit found in rural India
- Symptoms include burning sensation of the oral mucosa, increasing rigidity, and progressive inability to open the mouth (referred to as trismus), causing difficulties in swallowing, speaking, and eating
- Typically involves the buccal mucosa, lips, retromolar areas, and soft palate
- Fiery red (erythroplakic)-appearing areas
- Histologically, in more advanced lesions there is a dense submucosal collagen deposition characterized by thick bands of hyalinization with replacement of the submucosal soft tissues:
 - Hyalinization of minor salivary gland acini can be found.
 - Epithelium is often atrophic, but epithelial dysplasia can be present:
 - Intraepithelial dysplasia varies from 7% to 26%.
 - Ulceration and vesicle formation may occasionally occur.
- Up to 13% of patients with oral submucous fibrosis develop squamous cell carcinoma:
 - Development of squamous cell carcinoma is linked to the presence of tobacco as a component of areca nut
- No effective treatment for oral submucous fibrosis:
 - Restriction or elimination of areca nut use recommended
- Oral dysplasia and/or carcinoma associated with oral submucous fibrosis are treated as any other dysplasia or carcinoma.

Gingival Fibromatosis

Definition: Overgrowth of collagenous portion of non-epithelial gingival tissue.

- Unrelated to aggressive fibromatosis
- May be classified as follows:
 - Hereditary gingival fibromatosis
 - Idiopathic gingival fibromatosis
 - Drug-induced fibrous hyperplasia (also referred to as fibrous gingival hyperplasia)
- Hereditary gingival fibromatosis:
 - May present in early childhood with generalized (or localized) enlargement of attached gingiva
 - Gingiva is characterized as pink, firm, and very fibrous, with little tendency to bleed
 - Linked to a variety of syndromes, including:
 - Byars-Jurkiewicz syndrome (gingival fibromatosis, hypertrichosis, giant fibroadenomas of the breast, and kyphosis)
 - Cross syndrome (gingival fibromatosis, microphthalmia, mental retardation, athetosis, and hypopigmentation)
 - Gingival fibromatosis and growth hormone deficiency
 - Jones-Hartsfield syndrome (gingival fibromatosis and sensorineural hearing loss)
 - Murray syndrome (gingival fibromatosis with juvenile hyaline fibromatosis)
 - Ramon syndrome (gingival fibromatosis, hypertrichosis, cherubism, mental and somatic retardation, and epilepsy)
 - Rutherford syndrome (gingival fibromatosis and corneal dystrophy)
 - Prune-belly syndrome (hypoplastic abdominal muscle, cryptorchidism, obstructive nephropathy, gingival fibromatosis)
 - Zimmerman-Laband syndrome (gingival fibromatosis; ear, nose, bone, and nail defects; and hepatosplenomegaly)
 - Defect in the Son of sevenless-1 (*SOS1*) gene on chromosome 2p21-p22 (HGF1) as a possible cause of this clinical presentation
 - Transmitted through autosomal dominant and recessive modes
- Idiopathic gingival fibromatosis:
 - May present in early childhood with generalized gingival fibromatosis linked to a variety of syndromes or may appear as a papular lesion (papulosis or papular gingival fibromatosis) linked to

- such conditions as acanthosis nigricans, Cowden syndrome, and tuberous sclerosis
- Drug-induced fibrous hyperplasia:
 - Has been linked to a wide variety of drugs
 - Initially becomes noticeable 3 or more months after the use of the medication
 - Drugs associated with gingival fibrous hyperplasia include (but are not limited to):
 - Strongest association: phenytoin (Dilantin), cyclosporine, and nifedipine
 - Others include amlodipine, bepridil, bleomycin, diltiazem, felodipine, isradipine, nicardipine, nimodipine, nisoldipine, nitrendipine, oxidipine, sodium valproate, and verapamil
- A localized form of gingival fibromatosis is the symmetric fibromatosis of the tuberosity:
 - Appears to be a developmental type of phenomenon, although true cause is unknown
 - This form of fibrous hyperplasia may be more common than generalized gingival fibromatosis.

Pathology

- Share similar histology irrespective of clinical occurrence, including:
 - Dense or moderately dense relatively avascular submucosal collagenized connective tissue with scattered chronic inflammatory cells
 - Low cellularity consisting of fibroblasts interspersed with myofibroblasts
 - Myxoid change may be present rarely, calcifications identified

- Gingival epithelium may have extreme elongation of rete ridges including long, narrow anastomosing rete ridges extending into connective tissue
- Crevicular epithelium facing the tooth surfaces usually shows degeneration, subepithelial edema, and more extensive inflammatory cell infiltration due to gingivitis or periodontitis that is often present.

Treatment and Prognosis

- For generalized (hereditary) fibromatosis, treatment includes surgical excision, including gingivectomy and gingivoplasty, to recontour the tissue to achieve satisfactory cosmesis:
 - May recur or progress after surgery requiring repeated surgical resection
 - Improved oral hygiene greatly diminishes the risk of recurrence.
- Drug-induced gingival hyperplasia may also be treated by gingivectomy and plaque control:
 - Discontinuation of drug use often results in cessation and even regression of gingival enlargement.
- Symmetric fibromatosis of the tuberosity usually requires no treatment:
 - Large lesions or those that interfere with function or denture placement may be removed with conservative surgical excision.
 - Recurrence has not been reported.

NON-NEOPLASTIC OSSEOUS-RELATED LESIONS OF THE HEAD AND NECK

GIANT CELL GRANULOMA

(Figs. 5-28 through 5-30)

Definition: Reactive intraosseous and extraosseous proliferation containing numerous osteoclast-like giant cells.

NOTE:

- Because there is no histologic evidence to support a repair phenomenon, the designation “reparative” has been discarded.
- Giant cell granuloma shares many features with solid variant of aneurysmal bone cyst, and in many regards these lesions may be indistinguishable.
- Those lesions predominantly confined to intraosseous sites (e.g., jaws) are referred to as central giant cell granuloma:
 - Controversy whether these represent true neoplasms or reactive process

- Those lesions primarily involving soft tissues (e.g., sinonasal or oral mucosa) are termed peripheral giant cell granuloma:
 - Believed to represent a non-neoplastic reactive process likely occurring secondary to trauma or local irritation

Clinical

- For central (head and neck) lesions:
 - More common in women than in men; occur in patients under 30 years of age
 - Gnathic bones are the most common sites of occurrence:
 - Mandible > maxilla
 - Rare occurrences in other bones include paranasal sinuses and cranial bones.
 - Presents as a painless mass or swelling of affected site

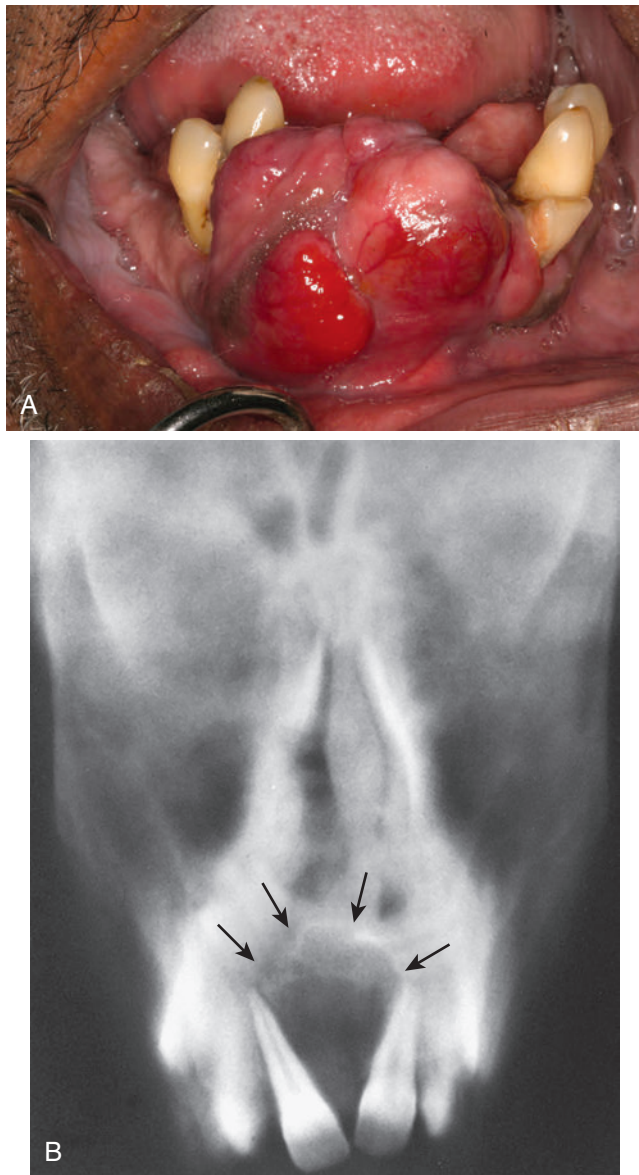

Fig. 5-28. Giant cell reparative granuloma.

A, Giant cell reparative granuloma. This patient presented with a protuberant soft tissue mass that involved bone. If the same lesion were entirely extraosseous, it would be designated as a peripheral reparative giant cell granuloma. **B**, Coronal multidirectional tomogram shows an expansile lesion in the maxillary alveolus and hard palate (arrows). This patient had a central-type giant cell granuloma. (A, Courtesy Dr. Mauricio Wiltz. B, From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, 4-207 and 4-208, p 359.)

Fig. 5-29. Central giant cell reparative granuloma.

A through **C**, Central giant cell reparative granuloma occurs in bone (upper right in **A**) and includes the presence of cellular fibrous stroma with numerous round to oval to spindle-shaped fibroblasts, variable numbers of multinucleated giant cells, numerous capillaries, and hemorrhage, including fresh hemorrhage and hemosiderin-laden macrophages (arrows in **B**); scattered mitotic figures may be present (arrow in **C**).

Fig. 5-30. Peripheral giant cell granuloma.

A through **C**, Peripheral (mucosal) giant cell granuloma is histologically similar/identical to central (intraosseous) lesions except that peripheral lesions are localized to a mucosal site without intraosseous involvement. To exclude osseous involvement clinical and radiologic correlation is required. The histologic findings include (**A**) presence of a submucosal proliferation lying subjacent to an intact surface epithelium (surface ulceration may be seen in some cases) composed of (**B, C**) cellular fibrous stroma with numerous round to oval to spindle-shaped fibroblasts, variable numbers of multinucleated giant cells, numerous capillaries, and hemorrhage.

- Radiographic appearance includes:
 - Demarcated, multiloculated, or soap bubble–appearing intraosseous lesion
 - Expansion and thinning of cortical plates
 - Displacement of teeth can be found.
- For peripheral lesions:
 - More common in women than in men; occur in patients under 30 years of age
 - Most often occurs in the oral mucosa (gingiva, alveolar mucosa) overlying the mandible and maxilla; sinonasal tract or nasopharyngeal involvement is uncommon
 - Presents as a painless, firm, sessile or pedunculated mucosal-based mass; overlying mucosa may be intact or ulcerated; sinonasal tract involvement may be associated with pain and swelling
- Radiographic appearance includes:
 - Superficial (not intraosseous) location with saucer-like erosion of subjacent bone
 - Expansion and thinning of cortical plates
- For central and peripheral lesions, laboratory values including serum calcium and phosphorus are within normal limits.
- Multiple lesions in the mandible, particularly if symmetric and bilateral, may suggest a diagnosis of cherubism:
 - Autosomal dominant disease with variable expressivity
 - Sporadic nonfamilial cases also reported

- Characterized by lateral swelling of the jaws (resembling cherubs in Renaissance paintings)
- Bilateral symmetric involvement is almost pathognomonic.
- Usually involves the mandible with the ramus always involved
- Patients have characteristic upturned appearance of the eyes resulting in a cherubic expression.
- Histologic features are those of giant cell granuloma; see below.
- Caused by mutation of *SH3BP2* gene on chromosome 4p16.3:
 - Mutations reported in 75% of cases
 - Mutation of the *SH3BP2* gene believed to increase production of overactive proteins from this gene
 - Overactive protein likely causes inflammation in jaw bones, triggering production of osteoclasts, which break down bone during bone remodeling
 - Bone loss and inflammation lead to increased fibrous tissue and cyst formation
 - Cherubism also found combined with other genetic disorders, including Noonan syndrome, Ramon syndrome, and fragile X syndrome

Pathology

- Central and peripheral giant cell granulomas are histologically identical and are composed of a cellular fibroblastic stroma that includes multinucleated giant cells:
 - Unencapsulated lesion composed of fibrous stroma with numerous round to oval to spindle-shaped fibroblasts, variable numbers of multinucleated giant cells and numerous capillaries, the latter often associated with a prominent endothelial cell proliferation
 - Copious foci of hemorrhage, including fresh hemorrhage and hemosiderin deposition; hemosiderin-laden macrophages are characteristically identified.
 - Giant cells are less diffusely distributed and tend to aggregate in and around foci of hemorrhage.
 - Less often, giant cells are diffusely distributed in the fibroblastic stroma.
 - Mitotic figures are seen in the fibroblasts but not the giant cells.
 - Cyst formation, bone, and osteoid may be present.
 - Peripheral giant cell granulomas are:
 - Submucosal lesions lying underneath an intact and uninvolved respiratory or squamous epithelium:
 - Surface epithelial ulceration may be present.
 - Separation of surface epithelium from subjacent giant cell granuloma by zone of uninvolved fibroconnective tissue
- Associated with chronic inflammatory cell infiltrate that may include mast cells (feature not typically seen in central lesions)
- Hemosiderin-laden macrophages typically seen along periphery of the lesion
- Immunohistochemistry:
 - Not necessarily used in the diagnosis and differential diagnosis
 - Identification of angiogenic factors, including vascular endothelial growth factor (VEGF) and basic fibroblastic growth factor (bFGF) in giant cells, may play a role in the process of osteoclastogenesis, potentially contributing to additional growth in these lesions.
- Cytogenetics and molecular genetics:
 - Lacks mutation of *SH3BP2* occurring in cherubism

Differential Diagnosis

- Giant cell tumor (see below)
- Brown tumor of hyperparathyroidism:
 - Given histologic similarity to brown tumor of hyperparathyroidism, prudent management includes laboratory evaluation of parathyroid gland function:
 - Increased serum levels of calcium, phosphate, alkaline phosphatase, and parathyroid hormone
 - See Section 9, Parathyroid Glands, for complete discussion.
- Aneurysmal bone cyst (ABC) (Figs. 5-31 and 5-32):
 - Represents a benign non-neoplastic osseous lesion characterized by the presence of numerous blood-filled cavities lacking an endothelial lining
 - Occurs as a de novo process unrelated/unassociated with an underlying pre-existing bone lesion or occurs in association with an underlying pre-existing bone lesion; the latter may include:
 - Giant cell tumor (most common)
 - Unicameral bone cyst
 - Osteosarcoma
 - Chondroblastoma
 - Nonossifying fibroma
 - Osteoblastoma
 - Fibrous dysplasia
 - Giant cell granuloma
 - Many other lesions
 - Most common site of occurrence is long bones, where they involve the metaphysis
 - Up to 12% of ABCs occur in the head and neck:
 - Most common site in the head and neck is the jaws with the mandible (body > ramus > angle > symphysis > condylar process) more common than the maxilla
 - Tends to occur in the first two decades of life

Fig. 5-31. Aneurysmal bone cyst.

A, Expansile multicystic radiolucent mandibular lesion eroding the cortices; a distinctive fluid level within the cyst (*arrowhead*) is seen. **B**, Resected specimen showing multiple blood-filled cysts and intercystic solid areas.

- Presents as a slowly or rapidly enlarging mass with associated swelling and pain; additional symptoms may include, depending on the site of occurrence, headache, visual disturbances (diplopia, decreased vision), proptosis, loosening of teeth, nasal obstruction, paresthesia, limitation of motion, fracture, facial nerve, or abducens nerve paralysis
- Occurrence in the sinonasal tract or nasopharynx may result in a soft tissue mass.
- Radiology:
 - Expansile, uni- or multilocular radiolucency surrounded peripherally by a thin shell of periosteal bone
- Histology:
 - Blood or blood-tinged serous fluid-filled cysts
 - Cysts lack an endothelial-lining and may be lined by fibroblasts, histiocytes, and/or multinucleated giant cells.

- Intercystic stroma is fibrous, well vascularized with mixed chronic inflammatory cells, extravasated erythrocytes and hemosiderin
- Almost all ABCs have areas in which the lesion is more or less solid characterized by a loose arrangement of spindle cells; increased mitotic activity (on average 1 to 3 mitoses per 10 high-power fields) are present but atypical mitoses are not identified
- Osteoid (lace-like), reactive bony trabeculae and osteoclastic giant cells are variably identified
- Mineralized/calcified matrix (so-called blue bone) is characteristically present in ABCs.
- Solid variant of ABC:
 - Characterized by firm and fleshy lesion completely solid microscopically lacking cystic cavities
 - Solid areas composed of spindle cell proliferation with giant cells and osteoid production similar in appearance to the solid areas of a “conventional” ABC
 - Of note, approximately 5% of ABCs lack cystic component.
- Histologic similarities to giant cell granuloma:
 - Differentiating feature is the presence of cysts seen in aneurysmal bone cyst, a feature typically not seen in giant cell granuloma.
 - Solid variant of ABC lacking cysts is histologically indistinguishable for giant cell granuloma.
- Treatment includes curettage or surgical resection:
 - Rate of local recurrence after curettage of the jaws ranges from 20% to 38%.
 - Recurrent lesions should also be managed conservatively.

Treatment and Prognosis

- For central lesions:
 - Conservative but complete surgical resection is the preferred treatment for gnathic and sinonasal lesions.
 - May behave in a locally aggressive manner
 - Recurrence rates vary and reported from 11% to near 50%
 - Radiation treatment generally not indicated
- For peripheral lesions:
 - Conservative but complete surgical resection to include the entire depth of the lesion with curettage of subjacent bone
 - May recur in a small percentage of cases (approximately 10%)

Fig. 5-32. Aneurysmal bone cyst.

A, Blood-filled cyst (*bottom center and right*) with more solid area characterized by spindle cell proliferation, scattered multinucleated giant cells (*arrows*) and lace-like osteoid (*arrowheads*). **B,** Higher magnification shows the blood-filled cyst (*bottom left*) lined by fibroblasts as well as giant cells (*arrowhead*); the solid area is composed of spindle cells and scattered multinucleated giant cells. **C,** Increased mitotic activity is present but atypical mitoses are not identified. **D,** Osteoid (lace-like) reactive bony trabeculae (*arrows*). **E,** Mineralized/calciified matrix (so-called blue bone) is a characteristic finding.

SELECTIVE AUTOIMMUNE, ALLERGIC, SYSTEMIC, CUTANEOUS-TYPE, AND MISCELLANEOUS DISEASES AFFECTING THE ORAL CAVITY

- Oral cavity may be involved by a wide variety of autoimmune, systemic, and cutaneous-type diseases (Box 5-2).
- Many of these lesions/diseases are beyond the scope of this text and the reader is referred to more detailed texts for a discussion of these disease entities.
- This section is limited to select diseases that the pathologist may confront in his/her daily practice.

GRANULOMATOSIS WITH POLYANGIITIS (GPA)

Definition: Non-neoplastic, idiopathic aseptic necrotizing disease with predilection for the upper/lower respiratory tract and the genitourinary system characterized by the presence of vasculitis and destructive properties. This classic definition calls for involvement of the head and neck region, the lung, and the kidney. The majority of GPA patients do not exhibit this classic clinical triad simultaneously at the time of initial presentation. Therefore, it is possible that, in a given patient, the initial biopsy material may originate from lesions of the UADT in the absence of a clinical suspicion for GPA.

- In the UADT, the most common site of occurrence is the sinonasal region with the nasal cavity > maxillary > ethmoid > frontal > sphenoid; other sites of involvement include nasopharynx, larynx (subglottis), oral cavity, ear (external and middle ear including the mastoid), and salivary glands.
- Oral manifestations of GPA may include:
 - An ulcerative lesion and gingivitis
 - Destructive lesions often seen along the palate and alveolar region
- For a more complete discussion see Section 1, Sino-nasal Tract.

RECURRENT APHTHOUS STOMATITIS (RAS)

Definition: Painful ulcerative disorder of unattached oral mucous membrane of unknown cause with tendency to recur.

Synonym: Canker sores

Clinical

- One of the more common recurrent ulcerative processes to affect the oral mucosa, affecting up to 10% to 15% of the world population
- Three clinical forms of aphthous stomatitis (AS) may occur, including minor AS, major AS, and herpetiform AS.

Minor Aphthous Stomatitis

- Most common clinical form of AS, accounting for 80% of cases
- More common in women than in men; often begins in childhood or adolescence
- May occur as a solitary lesion or in groups, tend to measure less than 1 cm in greatest dimension and heal within 7 to 10 days without scarring
- Lesions (ulcers) tend:
 - To occur on nonkeratinized mucosa with the buccal and labial mucosae representing the more common sites of occurrence; other sites of involvement include the tongue (ventral surface), floor of mouth, and soft palate:
 - Involvement of keratinizing mucosa, such as the gingival, hard palate, dorsal tongue, lip vermilion border) usually occurs as extension from an ulcer on an adjacent nonkeratinizing surface and rarely occurs as an isolated lesion of these keratinizing sites
 - To be painful, with the level of pain often out of proportion to the size of the lesion
 - To be covered by a white to yellow, mucopurulent exudate that is removable and is surrounded by an erythematous halo
- Recurrence rate of these ulcers varies from an ulcer every few years to several in a month.

Major Aphthous Stomatitis

- Occurs in a minority of patients (approximately 10%)
- Onset is usually after puberty, with recurring ulcers over decades
- Ulcers:
 - Are painful but are larger and deeper than the ulcers of minor AS
 - Occur over movable mucosa with soft palate, lip, and tonsillar regions most commonly affected, and may take several weeks to heal, with the resolution of the healing process resulting in submucosal scarring
 - May vary from a single ulcer to as many as 10 ulcers

Herpetiform Aphthous Stomatitis

- More common in women than in men; occur in adulthood

- Ulcers:
 - Tend to be smaller (1 to 2 mm) but are typically multiple, may coalesce into larger irregular ulcers
 - Most often occur on nonkeratinizing movable mucosa, take up to 10 days to heal, and have a higher frequency of recurrence over shorter periods of time
 - Resemble ulcers of herpes simplex virus, hence the designation herpetiform

General Comments

- Cause of AS:
 - Not known but thought to be multifactorial
 - Various considerations include trauma, stress, allergies, familial (genetic) predisposition, nutritional deficiencies, and infections (e.g., viral).
- AS has been associated with a number of systemic diseases, including Behçet disease, inflammatory bowel disease, celiac disease, Reiter disease, and immunocompromised conditions (e.g., AIDS/HIV disease).
- No specific laboratory findings associated with or diagnostic of AS:
 - In contrast to such lesions as GPA, serum anti-neutrophil cytoplasmic antibodies (ANCA), and proteinase 3 levels are not elevated in AS.
- Regional lymphadenitis may be present in association with the ulcers.

Pathology

Histology

- Nonspecific findings:
 - Early ulcers show central ulceration with associated fibrinopurulent exudates.
 - Deep to the ulcers there is increased vascularity and a mixed nonspecific acute and chronic inflammation of the submucosa.
- Because the histology is nonspecific and not in and of itself diagnostic for AS, diagnosis requires clinical correlation.
- Biopsies are necessary to exclude other diagnoses.
- Histochemistry:
 - Special stains for microorganisms are negative.
- Immunohistochemistry:
 - Increased activated cytotoxic T-lymphocytes and natural killer (NK) cells
 - Decreased CD4 lymphocytes

Differential Diagnosis

- Wide variety of other oral cavity ulcerative lesions, including (but not limited to):
 - Infections, vasculitic processes, and neoplasms:
 - Special stains for microorganisms may be required to exclude an infectious cause.

- Histologic findings of AS should allow for differentiating it from vasculitic lesions and neoplasms.

Treatment and Prognosis

- Solitary AS ulcers are usually self-limiting and require no therapy:
 - Topical steroids have been used in the treatment of the ulcers of minor AS.
 - Low-dose systemic corticosteroids have been used in the treatment of patients whose ulcers are not responsive to topical steroid.
 - Close monitoring for secondary oral candidiasis is required.
- A broad range of other medications are available with varying success, including antiseptics, anti-inflammatory drugs, and antibiotics (e.g., tetracyclines).
- For major ulcers, intralesional corticosteroid therapy may prove effective:
 - In patients with constant and aggressive outbreaks (major aphthae), pain is intense and topical treatment is unable to afford symptom relief.
 - In such cases, systemic therapy (e.g., corticosteroids) may be indicated.

ORAL LICHEN PLANUS (OLP)

(Fig. 5-33)

Definition: Immunologically mediated mucocutaneous disorder that often presents as a chronic dermatologic disease but also commonly affects the oral mucosa.

Synonym: Lichenoid mucositis

Clinical

- Represents the second most common site of occurrence to cutaneous sites:
 - Up to 35% of patients with LP have only oral manifestations.
- More common in women than in men; disease of middle-aged people; pediatric LP is uncommon (2% to 3%)
- May occur in several forms, including reticular (papular, plaque-like), erythematous (atrophic), and erosive (ulcerative or bullous):
 - Reticular and erosive forms are most common.
- Reticular form:
 - Most commonly affects the posterior buccal mucosa and may be bilateral; other sites of involvement include the tongue (lateral and dorsal), gingiva, palate, and lip (vermillion border)
 - Concurrent sites of involvement may occur.
 - Designation as reticular is due to the fact that the lesions have a characteristic pattern of interlacing white lines (so-called Wickham striae):

Fig. 5-33. Oral lichen planus.

A, Irregular epithelial hyperplasia with acanthosis, hyperkeratosis, and a saw-tooth configuration of the rete ridges with characteristic dense, bandlike chronic inflammatory cell infiltrate hugging the basal epithelium within the superficial submucosa. **B**, Dyskeratotic (apoptotic) basal keratinocytes (Civatte bodies) are present.

- In contrast, reticular OLP of the dorsal tongue appears as a keratotic plaque.
- Lesions of reticular OLP tend to be asymptomatic.
- Erosive form:
 - Often symptomatic with patients complaining of associated pain
 - Appear as atrophic, erythematous areas with central ulceration
 - Peripheral to the ulcer, interlacing white striations (Wickham striae) may be seen.
 - Gingival involvement may result in a clinical picture of desquamative gingivitis, necessitating biopsy to exclude other disease (e.g., cicatricial pemphigoid).

- In severe cases there may be epithelial separation, resulting in bullous form.
- Pathogenesis:
 - Unknown but evidence points to cell-mediated immune response
 - Numerous medications have been implicated in lesions that clinically simulate LP with similar histologic findings:
 - These lesions are referred to as lichenoid drug eruptions, and more specifically, relative to the oral mucosa have been termed lichenoid mucositis:
 - Appear to represent a systemic anaphylactic reaction
 - List of the medications associated with lichenoid drug eruption is extensive; a partial list includes antibiotics (ketoconazole, streptomycin, tetracycline), antihypertensive drugs (chlorothiazide, methyldopa, propranolol, spironolactone), nonsteroidal anti-inflammatory medication (naproxen, indomethacin, ibuprofen), antimalarials, and sulfonylureas

Pathology

Histology

- Overall histologic findings are not specific or pathognomonic but need to be correlated to the clinical picture to correctly diagnose the lesion.
- Epithelial alterations include:
 - Epithelial atrophy or acanthosis, hyperkeratosis (parakeratosis and orthokeratosis), and a saw-tooth configuration of the rete ridges
 - Hydropic degeneration (liquefaction) of the basal cell layer and dyskeratotic basal keratinocytes referred to as Civatte bodies
- In addition, a characteristic feature is presence of a dense, bandlike chronic inflammatory cell infiltrate predominantly composed of mature T-lymphocytes in the superficial submucosa hugging the basal epithelium.
- Absence of intraepithelial dysplasia:
 - Lesions with superimposed candida infection may appear dysplastic.
- Histochemistry:
 - Special stains for microorganisms are negative (except in the presence of fungal infestation).
- Immunohistochemistry:
 - Band-like lymphocytes are predominantly T-lymphocytes.
- Direct immunofluorescence:
 - Not diagnostic
 - Presence of fibrinogen in granular or linear pattern along basement membrane
 - Deposits of IgM, IgG, IgA, and C3 can be identified.

Differential Diagnosis

- Histologically, there are numerous pathologic processes with a lichenoid inflammatory reaction:
 - In contrast to LP, the inflammatory cell infiltrate in lichenoid lesions:
 - May have associated lymphoid follicles
 - May contain a higher number of plasma cells
 - May include a perivascular distribution

Treatment and Prognosis

- Treatment predicated on the extent of disease:
 - Reticular form:
 - Does not necessarily require treatment because it is often asymptomatic and may undergo spontaneous remission in more than 50% of cases
 - Superimposed fungal infection (e.g., candidiasis) requires antifungal therapy.

- Limited erosive form:
 - Topical corticosteroids used
- Extensive erosive form:
 - Systemic corticosteroids used
 - Close monitoring for secondary oral candidiasis is required.
- Whether the erosive form of LP can undergo malignant transformation is still debatable:
 - Development of squamous cell carcinoma in the setting of LP may be more coincidental than causative.

Neoplasms of the Oral Cavity

GENERAL CONSIDERATIONS

- Similar to tumors of other upper aerodigestive tract sites, the most common tumors of the oral cavity are of epithelial origin:
 - Most common benign tumor is a (squamous) papilloma
- Most common malignant tumor is squamous cell carcinoma or variant thereof
- Although epithelial neoplasms are the most common tumor type, other epithelial tumors including those of minor salivary gland origin, as well as nonepithelial tumors, occur in the oral cavity.

BENIGN NEOPLASMS

CLASSIFICATION OF ORAL CAVITY BENIGN NEOPLASMS (Box 6-1)

BOX 6-1 Classification of Neoplastic Lesions of the Oral Cavity

Benign

Epithelial

- Squamous papilloma
- Minor salivary gland tumors
- Ectomesenchymal chondromyxoid tumor of the anterior tongue
- Others

Mesenchymal/Neuroectodermal

- Peripheral nerve sheath tumors (e.g., schwannoma, neurofibroma, granular cell tumor, mucosa neuroma, others)
- Fibrous tumors (e.g., fibromatosis, myofibroma/myofibromatosis)
- Vascular neoplasms (e.g., angiofibroma, hemangioma, lymphangioma)
- Lipoma(s)
- Leiomyoma(s)
- Rhabdomyoma(s)
- Fibrous histiocytic tumors (e.g., fibrous histiocytoma)
- Osseous (e.g., ossifying fibroma, giant cell tumor, osteoma, osteoblastoma, others)
- Cartilaginous (e.g., chondroma, chondroblastoma, others)
- Others

Odontogenic

- Ameloblastoma
- Squamous odontogenic tumor
- Odontogenic keratocyst (keratocystic odontogenic tumor)
- Adenomatoid odontogenic tumor
- Calcifying epithelial odontogenic tumor
- Calcifying cystic odontogenic tumor
- Odontogenic myxoma/fibromyxoma

Malignant

Potentially Malignant Disorders

- Leukoplakia
- Proliferative verrucoid leukoplakia

- Erythroplakia
- Actinic cheilitis
- Keratinizing and nonkeratinizing dysplasias

Epithelial

- Squamous cell carcinoma including conventional-type and variants (e.g., verrucous carcinoma, papillary [exophytic] squamous cell carcinoma, spindle cell squamous carcinoma, basaloid squamous cell carcinoma, adenosquamous carcinoma, carcinoma cuniculatum, others)
- Minor salivary gland tumors
- Cribriform adenocarcinoma of minor salivary glands
- Others

Nonepithelial

- Mucosal malignant melanoma
- Neuroendocrine carcinomas
- Malignant hematolymphoid (e.g., non-Hodgkin lymphomas, Hodgkin lymphoma, plasma cell neoplasms)
- Sarcomas
- Rhabdomyosarcoma
- Leiomyosarcoma
- Liposarcoma
- Malignant peripheral nerve sheath tumors
- Fibrosarcoma
- Undifferentiated pleomorphic sarcoma
- Alveolar soft part sarcoma
- Angiosarcoma
- Kaposi sarcoma
- Matrix-forming malignant neoplasms (e.g., osteosarcoma, chondrosarcoma, others)
- Malignant odontogenic tumors
- Secondary neoplasms

PAPILLOMA (Figs. 6-1 and 6-2)

Definition: Benign, exophytic epithelial neoplastic growth composed of branching fronds of squamous epithelium with fibrovascular cores.

Synonym: Squamous papilloma

Clinical

- Most common benign neoplasm of the oral cavity
 - No gender predilection; most commonly seen in the third to fifth decades of life:
 - May occur in pediatric ages
 - Any site can be affected but most frequently involves tongue, palate, buccal mucosa, tonsil, and uvula
 - Symptoms relate to a painless mass.
 - Majority are solitary but may be multiple:
 - Multiple papillomas may occur in association with focal dermal hypoplasia syndrome or in focal epithelial hyperplasia (Heck disease)
 - Focal dermal hypoplasia:
 - Autosomal dominant disorder with incomplete penetrance
- Predominantly occurs in women
 - Features include:
 - Multiple papillomas
 - Dermal hypoplasia with fatty penetrance
 - Syndactyly
 - Colobomas of the iris and choroids
 - Strabismus
 - Ductal hypoplasia
 - Focal epithelial hyperplasia or Heck disease includes:
 - Multiple oral papillomas
 - Caused by HPV types 13 and 32
 - Papillomas may occur anywhere in the oral cavity but most common on the labial and buccal mucosa and the tongue
 - Florid oral papillomatosis:
 - Clinical term for diffuse papillomatous change but not a defined clinicopathologic entity
 - May be associated with:
 - Cowden syndrome:
 - ◻ Autosomal dominant disease characterized by facial trichilemmomas associated with

Fig. 6-1. Oral cavity squamous papillomas.

Squamous papillomas of the oral cavity include exophytic tan-white, warty or cauliflower-like lesions involving the (A) tongue, (B) tonsil, and (C) uvula.

Fig. 6-2. Histology of squamous papilloma.

Typical histologic features of squamous papilloma include (**A** and **B**) benign epithelial proliferation with fingerlike projections and fibrovascular cores lacking surface keratinization and intraepithelial dysplasia; increased mitotic figures can be seen (*arrowheads*) but there is retention of cellular polarity as well as maturation lacking features of dysplasia; (**C**) area of high-grade dysplasia in a papilloma characterized by loss of polarity, nuclear pleomorphism and hyperchromasia, with increased nuclear-to-cytoplasmic ratio, increased mitotic activity including atypical mitoses and dyskeratotic cells (*arrowhead*); (**D**) squamous papilloma with transformation to carcinoma in situ showing transition from benign epithelium (*right*) to areas of carcinoma in situ (*left*); invasive squamous cell carcinoma was present (not shown).

GIT, CNS, musculoskeletal, and thyroid abnormalities

- Down syndrome, nevus unis lateris syndrome (ichthyosis hystrix), acanthosis nigricans, tuberous sclerosis, and focal dermal hypoplasia syndrome (Goltz-Gorlin syndrome)
- Immunosuppressed patients, in particular HIV infection, may be associated with florid oral papillomas/papillomatosis (immunodeficiency and papillomas/papillomatosis):
 - Entire oral mucosa may be papillomatous.
 - Lesions tend to be larger than nonimmunosuppressed-related lesions and may be

multiple; lesions may coalesce to form extensive mucosal patches.

- Multiple HPV subtypes, including unusual ones, may be identified.
- Cause:
 - Human papillomavirus (HPV) proposed as causative:
 - Many HPV subtypes have been detected, but most common are HPV types 6 and 11.
 - HPV DNA identified in greater than 80% of cases
 - No definitive association between HPV type and the type of papilloma

Pathology

Gross

- Exophytic, pink to tan-white lesion with a warty or cauliflower-like appearance; variation in size from a few millimeters up to 3.0 cm in greatest dimension

Histology

- Multiple finger-like projections with prominent fibrovascular cores covered by hyperplastic squamous epithelium:
 - Typically there is an absence of keratosis.
 - Squamous cell component generally is free of any dysplastic change.
 - Variable amount of hyperkeratosis, parakeratosis, and orthokeratosis may be seen.
 - On rare occasions, an “inverted” growth may be seen.
- Viral-associated cytopathic changes (i.e., koilocytes) may be seen in uppermost epithelial cell layers.

Differential Diagnosis

- Verruca vulgaris
- Syringocystadenoma papilliferum
- Verrucous carcinoma
- Exophytic squamous cell carcinoma
- Inflammatory papillary hyperplasia:
 - Benign, reactive oral epithelial hyperplasia often associated with an intraoral inflammatory process (e.g., stomatitis)
 - Relatively common oral lesion
 - More common in men than in women; typically occur in the third through fifth decades of life
 - May occur in any intraoral site but is most often found on the palate
 - Painless, appearing as multiple warty or papillary, red-appearing lesions
 - Development linked to:
 - Patients with stomatitis, the result of ill-fitting dentures or dental prostheses, especially in those people who retain their prosthesis while sleeping and who exhibit poor oral hygiene
 - *Candida*
 - May also occur in dentulous patients without known history of dental prosthesis use
 - Histologically:
 - Similar to pseudoepitheliomatous hyperplasia with hyperkeratosis, parakeratosis, and an absence of epithelial dysplasia
 - Edematous change and a mixed chronic inflammatory cell reaction can be seen in the submucosa.
 - Secondary reactive or degenerative changes of seromucous glands, including squamous metaplasia, fibrosis, atrophy, mucin pool formation, and mixed inflammation may be present in

areas overlying minor salivary glands; despite these findings the lobular configuration of the seromucous glands is retained.

- Fungi (i.e., *Candida albicans*) may be present.
- Resolution may occur by initial treatment approach that includes:
 - Replacement of prosthesis with a better fitting one and education in the proper oral hygiene indicated
 - Topical antifungal (e.g., miconazole) used to treat presence of fungi
- Failure for lesions to regress/resolve after conservative (nonsurgical) approach may require surgical excision
- Not considered to be a premalignant lesion

Treatment and Prognosis

- Complete surgical excision usually is curative.
- Recurrences occur infrequently and relate to inadequate excision.
- Malignant transformation does not occur.

BENIGN MINOR SALIVARY GLAND TUMORS

- Benign salivary gland tumors of the oral cavity are fairly common.
- Pleomorphic adenoma is the dominant histologic type seen; less often, monomorphic adenomas such as myoepithelioma and oncocytoma occur.
- For a more complete discussion see Section 6, Salivary Glands.

Ectomesenchymal Chondromyxoid Tumor of the Anterior Tongue

(Figs. 6-3 and 6-4)

Definition: Benign tumor of the anterior dorsal tongue of presumed origin from an undifferentiated ectomesenchymal cell but owing to morphologic and immunohistochemical resemblance to soft tissue myoepitheliomas it is more likely a myoepithelial neoplasm of soft tissues.

Synonyms: Oral myoepithelioma of soft tissue origin; reticulated myxoid tumor of the tongue; myoepithelioma of the tongue

Clinical

- Uncommon tumor
- No gender predilection; occurs over wide age range including first to eighth decades of life; median age of 32 years
- Asymptomatic, slow-growing, painless, submucosal nodular lesion of the anterior dorsal tongue

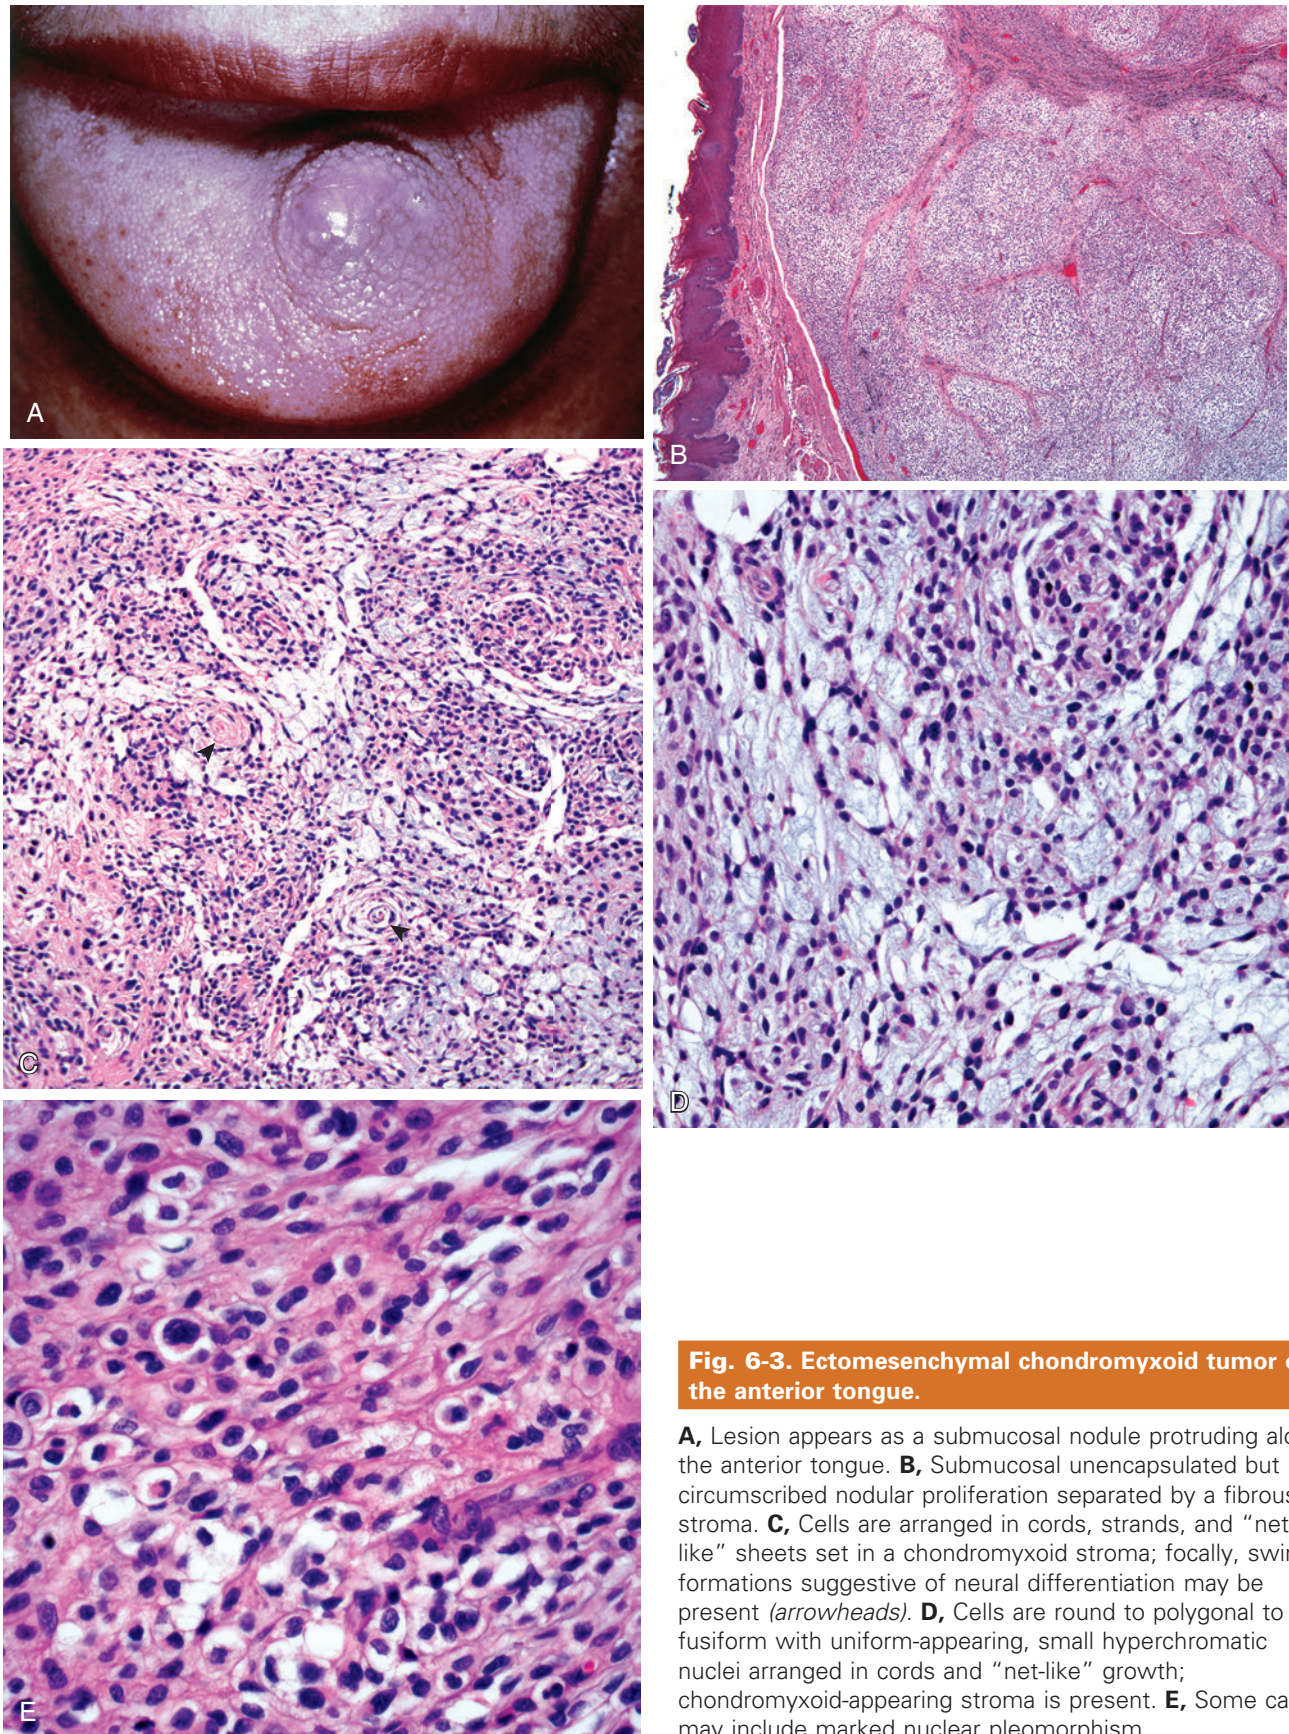

Fig. 6-3. Ectomesenchymal chondromyxoid tumor of the anterior tongue.

A, Lesion appears as a submucosal nodule protruding along the anterior tongue. **B**, Submucosal unencapsulated but circumscribed nodular proliferation separated by a fibrous stroma. **C**, Cells are arranged in cords, strands, and "net-like" sheets set in a chondromyxoid stroma; focally, swirling formations suggestive of neural differentiation may be present (*arrowheads*). **D**, Cells are round to polygonal to fusiform with uniform-appearing, small hyperchromatic nuclei arranged in cords and "net-like" growth; chondromyxoid-appearing stroma is present. **E**, Some cases may include marked nuclear pleomorphism.

Continued

Fig. 6-3, cont'd

F, Nodular foci with chondromyxoid stroma. **G**, Infiltration and entrapment of skeletal muscle may be identified.

Pathology

Gross

- Submucosal nodular growth appearing tan-yellow and measuring from 0.5 to 3 cm in greatest dimension; on cut section has a gelatinous appearance/consistency

Histology

- Submucosal unencapsulated but well-delineated or circumscribed nodule(s) separated by a fibrous stroma
- Cells are round to polygonal to fusiform with uniform-appearing small hyperchromatic nuclei and ample basophilic-appearing cytoplasm.
- Cells may be arranged in cords, strands, and so-called net-like sheets set in a chondromyxoid stroma; hyalinized foci may be present.
- Generally, nuclear pleomorphism, multinucleation, and mitotic figures are not present but in occasional cases hyperchromatic and pleomorphic nuclei as well as mitotic figures may be identified.
- Atypical mitoses and necrosis are not identified.
- Swirling formations suggestive of neural differentiation may be present.
- Absence of glands and/or myoepithelial cells (spindle shaped, plasmacytoid)
- Lesional cells may extend into and/or entrap soft tissue structures, including:
 - Skeletal muscle
 - Nerves

- Histochemistry:
 - Tumor cells:
 - Mucicarmine, periodic acid Schiff with and without diastase negative
 - Extracellular matrix:
 - Alcian blue (pH 0.4 and 2.5) positive
 - Mucicarmine faintly positive
- Immunohistochemistry:
 - Glial fibrillary acidic protein (100%), cytokeratins (>90%), S100 protein (60%), smooth muscle actin (>50%); vimentin positive
 - Epithelial membrane antigen, desmin negative
 - No reports include staining for p63 or calponin.
- Electron microscopy (limited to a single case):
 - Presence of partial basal lamina
 - Absence of desmosomes or thin filaments
- Cytogenetics and molecular genetics:
 - No reported cases with *EWSR1* gene rearrangements as identified in association with soft tissue myoepitheliomas

Differential Diagnosis

- Monomorphic adenoma of salivary glands:
 - Myoepithelioma:
 - Myoepithelioma of the anterior dorsal tongue is rare.
 - Immunohistochemical findings would be compatible with myoepithelial cells, but presence of chondromyxoid stroma and absence of plasmacytoid and/or spindle-shaped myoepithelial

Fig. 6-4. Immunohistochemical reactivity in ectomesenchymal chondromyxoid tumor.

Lesional cells of ectomesenchymal chondromyxoid tumor may show immunoreactivity for (A) GFAP (positive in 100% of cases), (B) cytokeratin, (C) S100 protein, (D) smooth muscle actin.

- cells by light microscopy weigh against this diagnosis.
- Pleomorphic adenoma:
 - Rarity of salivary gland tumors localized to the anterior dorsal tongue and absence of identifiable glandular differentiation by light microscopy weigh against this diagnosis.
- Extraskeletal myxoid chondrosarcoma:
 - Location is rare for chondrosarcomas of any type
 - Presence of cytokeratin and glial fibrillary acidic protein are not features seen in chondrosarcomas.

Treatment and Prognosis

- Conservative but complete excision is curative
- Rarely (<10%) recur; recurrence likely a function of inadequate excision

MESENCHYMAL NEOPLASMS

Benign Peripheral Nerve Sheath Neoplasms

General Considerations

- Benign peripheral nerve sheath tumors include neurilemoma and neurofibroma (see Section 4, Neck).
- Other benign tumors of nerve sheath or presumed peripheral nerve sheath origin include:
 - Granular cell tumor
 - Mucosal neuroma
 - Palisaded encapsulated neuroma (solitary circumscribed neuroma)
 - Dermal nerve sheath myxoma (neurothekeoma) (see Section 4, Neck)
 - Perineurioma (see Section 4, Neck)
- See Section 5, Larynx, for discussion of mucosal granular cell tumor.

Granular Cell Tumor

Definition: Benign tumor of neural (Schwann cell) origin.

- Two forms of granular cell tumor can occur:
 - Mucosal granular cell tumor
 - Congenital granular cell epulis

Mucosal Granular Cell Tumor

- See Section 6, Larynx, for a more complete discussion, including illustrations.

Congenital Granular Cell Epulis

(Fig. 6-5)

Synonyms: Congenital epulis; gingival granular cell tumor of newborn; congenital granular cell myoblastoma.

- Use of the term epulis refers to any mass on the gingiva.

Clinical

- More common in females than males; occurs exclusively in newborns (at or immediately after birth)
- Identified on gum pads in oral cavity on the crest of the alveolar ridge in the incisor region:
 - Localizes to labial aspect of the dental ridge with a predilection of the upper jaw
- Affects the maxilla more often than the mandible but can occur in both locations simultaneously
- Approximately 10% are multiple.

Fig. 6-5. Congenital granular cell epulis.

A, Newborn with a polypoid mass on the anterior mandibular ridge. **B**, Cells are similar to those seen in granular cell tumor but there is a greater degree of vascularity characterized by arborizing capillaries; although not shown, other features that contrast from granular cell tumors include absence of associated pseudoepitheliomatous hyperplasia, incorporation of odontogenic epithelium, absence of S100 protein, and presence of vimentin, neuron-specific enolase, and CD68 immunoreactivity.

- Radiology:
 - May be diagnosed prenatally by ultrasound:
 - Ultrasound examination shows marked blood flow in the tumor.
- Histogenesis:
 - Owing to absence of S100 protein reactivity, this tumor is felt to originate from a non-neural cell of origin but the histogenesis remains uncertain.
 - Some authorities believe it to be a nonneoplastic (hamartomatous) lesion.

Pathology

Gross

- Smooth, pink multilobulated mass ranging in size from millimeters up to 5 cm

Histology

- Similar to granular cell tumor with the following exceptions:
 - Greater degree of vascularity
 - Absence of associated pseudoepitheliomatous hyperplasia
 - Less conspicuous nerve bundles
 - Incorporation of odontogenic epithelium may be seen
 - Absence of S100 protein and laminin immunoreactivity
 - Immunoreactivity for:
 - Vimentin, CD68 (KP1), alpha-1-antitrypsin
 - Smooth muscle differentiation may be present.

Treatment and Prognosis

- Usually require complete surgical excision
- May regress spontaneously

Mucosal Neuroma (Fig. 6-6)

Definition: Benign tumor of nerve sheath origin involving mucosal surfaces of the oral cavity, eyelids, and intestines occurring associated with multiple endocrine neoplasia (MEN) syndrome type 2B.

Synonyms: Multiple endocrine neoplasia 2B-associated mucosal neuroma; oral mucosal neuroma

- MEN 2B (see Section 10 for a more complete discussion):
 - Occurs sporadically or inherited in autosomal dominant manner
 - Caused by germline mutations of *RET* proto-oncogene
 - Characterized by:
 - Medullary thyroid carcinoma
 - Pheochromocytoma
 - Parathyroid proliferative disease (adenoma, hyperplasia)
 - Mucosal neuromas, intestinal ganglioneuromatosis, and musculoskeletal abnormalities

Fig. 6-6. Oral mucosal neuroma.

Oral mucosal neuroma in a patient with multiple endocrine neoplasia (MEN) syndrome type 2B. **A**, Multiple nodules of the anterior tongue. **B** and **C**, Submucosal proliferation of irregular tortuous bundles of nerves with prominent perineurium.

Clinical

- Slightly more common in females than males; noted at birth or during first few years of life
- Common sites of involvement include lips, tongue, and eyelids:
 - Oral cavity:
 - Vermilion border of the lips, anterior third of the ventral or dorsal tongue, buccal mucosa
 - Ocular:
 - Eyelids
- Clinical appearance includes the presence of multiple small, sessile, mucosal-covered nodules.

Pathology

Histology

- Polypoid, dome-shaped, or diffuse submucosal proliferation of numerous irregular tortuous, highly branched and loosely arrayed nerves of varying size with prominent perineurium and presence of focal myxoid change:
 - Perineurium of affected nerve is thickened.
 - Mucoïd or myxoid endoneurial matrix may separate nerve fibers.
 - Reactive perineurial fibrosis not a feature.
 - Absence of ganglion cells (present in intestinal ganglioneuromatosis, noted in cases of mucosal neuromas of lingual and ciliary nerves and lesions in the roof of the iris and uveal meshwork)
- Immunohistochemistry:
 - S100 protein positive (Schwann cells)
 - Neurofilament protein positive (axons)

Differential Diagnosis

- Traumatic (amputation) neuroma:
 - Exuberant, non-neoplastic proliferation of nerves occurring in response to injury or surgery
 - Presents as firm nodule occasionally tender or painful
 - Circumscribed nodule(s) located in continuity with proximal end of injured or transected nerve
 - Unencapsulated lesion consisting of haphazard proliferation of nerve fascicle including axons Schwann cells and fibroblasts:
 - Less well-myelinated than parent nerve
 - Enveloped in collagen
 - May be embedded in mucoïd matrix
 - Immunoreactivity present for neurofilament protein (axons), S100 protein (Schwann cells), and EMA (perineurial cells)
- Plexiform neurofibroma
- Palisaded encapsulated neuroma (solitary circumscribed neuroma) (Fig. 6-7):
 - Distinct form of true neuroma consisting of Schwann cells as well as axons within a perineurial-derived capsule

- No association with NF-1 or MEN 2B
- Usually a cutaneous lesion
- May occur in the oral cavity (palate, lips)
- Small asymptomatic solitary circumscribed nodule
- No gender predilection; occurs in adults
- Histology:
 - Submucosal circumscribed nodular or multinodular, solid proliferation of Schwann cells lacking stromal alterations, including hyalinization or myxoid change often associated with schwannomas or neurofibromas
 - Most are small, measuring approximately 3 mm, and localized to the reticular dermis or submucosa.
 - In spite of its description most do not show “palisading” and are not encapsulated but often are incompletely encapsulated.
 - Composed of bland-appearing spindle cells set in a variably fibrous stroma and focally separated by artifactual clefts or cracking artifact:
 - Clefts or cracks likely related to fixation
 - Surrounds or results in slit-like spaces between cell bundles
 - Schwann cells are diffusely and strongly S100 protein positive.
 - Presence of axons traverse the lesion in close association with Schwann cells:
 - Not evident on hematoxylin and eosin staining
 - Best seen with silver stains
 - May be highlighted by neurofilament protein (NFP) immunostaining
- Simple surgical excision is curative.

Treatment and Prognosis

- Surgical excision may be performed for cosmetic purposes.
- Diagnosis should prompt work-up for possibility of MEN 2B:
 - Early diagnosis of MEN 2B, especially evaluation for the possibility of medullary thyroid carcinoma, allows for initiation of earlier treatment.

BENIGN FIBROUS TUMORS

Fibromatosis/Extraabdominal Fibromatoses

Definition: Locally aggressive, nonmetastasizing (myo) fibroblastic neoplasm characterized by locally infiltrative growth.

Synonyms: Desmoid-type fibromatosis; desmoid tumor; aggressive fibromatosis; extraabdominal desmoid, extraabdominal fibromatosis; tumefactive fibroinflammatory tumor; inflammatory pseudotumor

Fig. 6-7. Palisaded encapsulated neuroma (solitary circumscribed neuroma).

A, Submucosal circumscribed but not encapsulated nodular, solid proliferation of Schwann cells. **B**, Bland-appearing spindle cells set in a variably fibrous stroma and focally separated by artifactual clefts or cracking artifact (*arrowheads*). **C**, Diffuse and strong S100 protein staining. **D**, Neurofilament protein (NFP) immunostaining highlights axons traversing the lesion in close association with Schwann cells.

- See Section 5, Neck, for a more complete discussion.
- Fibromatosis of the head and neck region occurs primarily in the soft tissues of the neck, including the supraclavicular region and the anterolateral neck.
- Excluding the neck, the common sites of occurrence are the sinonasal tract, nasopharynx, tongue, and oral cavity.
- Approximately 10% to 15% of fibromatoses occur in the head and neck; in children, more than one third of cases occur in the head and neck.

Myofibroma and Myofibromatosis (Fig. 6-8)

Definition: Benign neoplasm composed of myoid cells arranged around thin-walled blood vessels.

- Two types:
 - Solitary (myofibroma)
 - Multicentric (myofibromatosis)
- Synonym:** Infantile myofibromatosis

Clinical

- Myofibromas:
 - Most common type occurring three times more often than multicentric form
 - More common in males than females; occurs over a wide age range, including infants and adults but represents the type most commonly seen in adults
 - Tend to occur in the head and neck region:
 - Most common in bone (mandible and skull) followed by the oral cavity, especially the buccal mucosa and tongue; less common intra-oral sites of involvement include the gingival, palate, lip, retromolar trigone

Fig. 6-8. Oral myofibroma.

A, Submucosal nodular growth. **B**, Nodule composed of spindle-shaped cells with elongated, cigar-shaped vesicular nuclei arranged in short fascicle at periphery with round cells having round to polygonal to spindle-shaped hyperchromatic nuclei and scant eosinophilic cytoplasm more centrally located. **C**, Irregularly branching blood vessels similar in appearance to those associated with hemangiopericytoma. **D**, Subendothelial intravascular growth. **E**, Diffuse immunoreactivity for smooth muscle actin.

- May rarely involve other head and neck sites, including sinonasal tract and neck
- Presents as a painless mass usually measuring less than 3 cm
- Myofibromatosis may occur with or without visceral involvement:
 - Without visceral involvement:
 - More common in males than females; majority (up to 90%) occurs within the first 2 years of life with many presenting at birth
 - Sites of involvement include skin, subcutis, soft tissue, and bone:
 - Multiple lesions may be limited to a single general anatomic site (e.g., only head and neck) or may be generalized in distribution
 - Absence of visceral involvement
 - Presents as a painless mass usually measuring less than 3 cm
 - Possible but not definitive for familial inheritance
 - With visceral involvement:
 - Up to 40% have visceral involvement
 - More common in males than females; majority (up to 90%) occur within the first 2 years of life with many presenting at birth
 - Sites of involvement include skin, subcutis, soft tissue, and bone as well as visceral involvement, the latter including:
 - Lungs, heart, gastrointestinal tract, liver, kidney, pancreas, and rarely central nervous system
 - Present with symptoms related to the organs involved
 - Possible but not definitive for familial inheritance
- Radiology:
 - Osseous lesions appear as circumscribed radiolucent lesions often with sclerotic margin
 - Central mineralization may be present.
- Familial occurrence has been reported:
 - Inherited in autosomal dominant manner
- Peripheral (light staining) zone composed of plump-appearing, spindle-shaped cells with elongated, cigar-shaped vesicular nuclei, small nucleoli, and pale pink cytoplasm; cells are arranged in short fascicles or whorls
- Central (dark staining) zone composed of primitive-appearing round cells with round to polygonal to spindle-shaped, vesicular to hyperchromatic nuclei, and scant eosinophilic to clear cytoplasm arranged around thin-walled, irregularly branching blood vessels showing features similar to the vascularity seen in hemangiopericytomas
- No significant pleomorphism or increase in mitotic activity
- Extensive coagulative necrosis may be identified.
- Hemorrhage, cystic degeneration, calcification, and stromal hyalinization may be focally present.
- Intravascular growth is frequently present:
 - Subendothelial location
 - No prognostic significance
- Peripherally located chronic inflammatory cells, including lymphocytes and plasma cells, may be present.
- Immunohistochemistry:
 - Vimentin positive
 - Actins (smooth muscle and muscle specific) focally and weakly positive
 - S100 protein, desmin, and epithelial markers are negative.
 - Proliferation rate indices of up to 10% seen by Ki67 (MIB1) staining
- Electron microscopy:
 - Findings compatible with myofibroblasts, including prominent rough endoplasmic reticulum, intracytoplasmic filament bundles with dense bodies, and focal basal lamina
- Cytogenetics and molecular genetics:
 - Absence of *ETV6-NTRK3* gene fusion that is identified in infantile fibrosarcoma

Pathology

NOTE: Pathologic findings remain similar, whether solitary or multifocal.

Gross

- Well-circumscribed, rubbery to firm, gray-white to tan-brown mass ranging in size from 0.5 to 7 cm with a median size of 2.5 cm
- Degenerative changes may be present, including cyst formation, hemorrhage, and necrosis.

Histology

- Nodular or multinodular growth with characteristic biphasic or “zoning” appearance due to regional variation of cell types, including:

Differential Diagnosis

- Fibromatosis
- Nodular fasciitis
- Smooth muscle neoplasms (leiomyoma, leiomyosarcoma)
- Sarcomas:
 - Due to increased cellularity, rich vascularity, and presence of necrosis, myofibromas/myofibromatosis may be mistaken for a sarcoma.

Treatment and Prognosis

- Spontaneous regression may occur in solitary or multifocal (without visceral involvement) lesions.
- Simple excision of solitary lesions is curative.
- Surgical resection of multiple lesions may be indicated in cases in which there is functional impairment or involvement of vital organs.

- Recurrence rates after surgery usually are less than 10% of cases.
- Prognosis less favorable in newborns and infants with multiple visceral lesions:
 - Increased morbidity and mortality:
 - Mortality rates >70% reported
 - Death may be due to cardiopulmonary or gastrointestinal complications.
 - Low-dose chemotherapy (methotrexate and vinblastine) may be effective in treating patients with multicentric visceral involvement.

BENIGN VASCULAR TUMORS

- See Section 1 on the Sinonasal Tract for a more complete discussion.
- May include a variety of hemangioma subtypes, including capillary, cavernous, mixed capillary-cavernous
- Majority occurs in adults
- Most common sites of occurrence include lips, buccal mucosa, and tongue.
- These tumors may be mucosal based or within muscle (intramuscular) or bone (intraosseous).

BENIGN LIPOGENIC TUMORS

- Benign lipogenic tumors of the oral cavity are uncommon.
- See Sections 4, Neck, and 5, Larynx and Trachea, for discussion.

BENIGN MYOGENIC TUMORS

- Benign myogenic tumors of the oral cavity are uncommon and include tumors of smooth muscle differentiation (leiomyomas) and skeletal muscle differentiation (rhabdomyomas).
- For leiomyoma see Section 1, Sinonasal Tract.
- For rhabdomyoma see Section 4, Neck.

BENIGN FIBROHISTIOCYTIC TUMORS

- Benign fibrohistiocytic tumors of the oral cavity are uncommon and include fibrous histiocytoma; see Section 1, Sinonasal Tract.

BENIGN FIBRO-OSSEOUS LESIONS OF CRANIOFACIAL BONES (Table 6-1)

- Gnathic (jaw bones) benign fibro-osseous lesions include ossifying fibromas (and variants thereof) and fibrous dysplasia.

- Fibrous dysplasia is not a neoplastic lesion but is included here as part of the broader category of benign fibro-osseous lesions.
- Gnathic fibro-osseous lesions (ossifying fibroma and fibrous dysplasia) may be histologically indistinguishable; therefore a definitive diagnosis may not be achievable on morphology alone, and the diagnosis rests on the clinical-radiologic-histopathologic correlation.
- In the head and neck, benign fibro-osseous lesions occur most often in relation to gnathic (maxillary and mandibular) bones.
- Given its localization to the sinonasal tract, psammomatoid ossifying fibroma is discussed in Section 1, Sinonasal Tract.

Ossifying Fibroma (Fig. 6-9 and 6-10)

Definition: Well-demarcated, slow-growing benign fibro-osseous neoplasm composed of fibrocellular tissue admixed with varying amounts of mineralized material (i.e., bone, cementum) of varying appearances.

Synonyms: Cemento-ossifying fibroma; cementifying fibroma; central intraosseous ossifying fibroma; fibrous osteoma; osteofibroma

Clinical

- More common in women than men; occurs over a wide age range but is most frequently seen in the second to fourth decades of life
- Most common site of occurrence is the mandible, especially molar or posterior area followed by the premolar area, incisor area, and cuspid area
 - May also occur in association with the maxilla, but maxillary involvement occurs much less often as compared with the mandibular region
- Generally asymptomatic unassociated with pain or swelling and diagnosed incidentally after radiographic examination; symptomatic tumors manifest by displacement of teeth or as an expansile mass that may include facial asymmetry.
- Typically presents as solitary mass but infrequently may be multifocal:
 - Multifocal tumors can occur in the mandible, in the maxilla, or in both regions.
 - Polyostotic involvement of extragnathic bones as seen in fibrous dysplasia is not a finding associated with ossifying fibromas.
- Radiology:
 - Well-circumscribed lesion with smooth contours having a variation in appearance based on the maturity of the tumor, including:
 - Completely radiolucent:
 - Immature lesion
 - Completely radiopaque:
 - Mature lesion

TABLE 6-1 Benign Fibro-osseous Lesions: Clinicopathologic Comparison

	OF	POF	FD
Gender/age	F > M; 2nd-4th decades	F = M; younger age groups (1st-2nd decades), but may occur in older individuals	MFD: F = M; 2nd-3rd decades PFD: F > M; 1st decade
Location	Most common in the mandible (posterior or molar region)	Ethmoid sinus; supraorbital frontal region	No specific site of involvement
Focality	Single site	Single site or involvement of multiple (contiguous) sites/sinuses	MFD (75%-80%) PFD (20%-25%) MAS (1%-3%)
Radiology	Well-circumscribed or sharply demarcated lesion with smooth contours	Lytic or mixed lytic/radiopaque osseous and/or soft tissue mass varying from well demarcated to invasive with bone erosion	Poorly defined expansile osseous lesion with a thin intact cortex; predominantly fibrous lesions are radiolucent; predominantly osseous lesions are radiodense; lesions with an equal admixture of fibrous and osseous components have a ground glass appearance
Histology	Randomly distributed mature (lamellar) bone spicules rimmed by osteoblasts admixed with a fibrous stroma; central portions may be woven bone with lamellar bone at the periphery	Bony spicules and distinctive mineralized or calcified "psammomatoid" bodies or ossicles admixed with a fibrous stroma; psammomatoid bodies vary from a few in number to a dense population of innumerable spherical bodies; osteoclasts are present within the ossicles, and osteoblasts can be seen along their peripheral aspects; the bony trabeculae vary in appearance and include odd shapes with a curvilinear pattern; trabeculae are composed of lamellar bone with associated osteoclasts and osteoblastic rimming.	Fibrous tissue component is nondescript and of variable cellularity; osseous component includes irregularly shaped trabeculae of osteoid and immature (woven) bone that is poorly oriented with misshapen bony trabeculae with odd geometric patterns including C- or S-shaped configurations; the trabeculae typically lack osteoblastic rimming
Syndromes	No known association	No known association	MAS (1% to 3%)
Treatment	Surgical resection	Surgical resection	Disease may stabilize at puberty and, in children, therapy should be delayed if possible until after puberty; surgical resection indicated in cases with compromise of function, progression of deformity, associated pathologic fracture(s), or the development of a malignancy
Prognosis	Excellent	Good after complete excision; recurrence(s) often occurs due to incomplete excision; may behave in an aggressive manner with local destruction and potential invasion into vital structures	Good prognosis; recurrence rates are low and death due to extension into vital structures rarely occurs
Malignant transformation	Not known to occur	Not known to occur	Malignant transformation (osteosarcoma) occurs in less than 1%; dismal prognosis

FD, Fibrous dysplasia; MAS, McCune-Albright syndrome; MFD, monostotic fibrous dysplasia; OF, ossifying fibroma; PFD, polyostotic fibrous dysplasia; POF, psammomatoid ossifying fibroma.

Fig. 6-9. Ossifying fibroma in the mandible.

A, Pantomogram of the mandible. **B**, Axial CT image shows a homogeneous radiopaque internal structure (*arrow*) and radiolucent band at the periphery (*arrowheads*). **C**, Axial T1-weighted MR image shows an intermediate signal intensity. **D**, Axial T2-weighted MR image shows a heterogeneous intermediate signal intensity. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 25-62, p 1509.)

- Mixed radiolucent and radiopaque:
 - Increased mineralization with age results in radiopaque foci admixed with radiolucent areas
- Presumptive origin is from the periodontal ligament, which:
 - Is a layer of fibrous connective tissue surrounding and attaching the roots of teeth to alveolar bone
 - Is capable of forming cementum, bone, and fibrous tissue
 - Supports close relationship to cementifying fibroma and cemento-ossifying fibroma; in fact, all of these lesions are considered variants of ossifying fibroma

Pathology

Gross

- Well-demarcated, tan/gray to white, gritty and firm lesions varying in size from 0.5 to as large as 10 cm

Histology

- Well-delineated, demarcated, or encapsulated proliferation composed of randomly distributed mature (lamellar) bone spicules rimmed by osteoblasts admixed with a fibrous stroma
- Although the osseous component is generally described as mature, the central portions may be woven bone with lamellar bone at the periphery.

Fig. 6-10. Ossifying fibroma.

Histologically, ossifying fibroma is characterized by an admixture of mature (lamellar) bone and a fibrous stroma; bony spicules are rimmed by osteoblasts. The fibrous stroma is similar to that seen in fibrous dysplasia. Although these features support a diagnosis of ossifying fibroma, there are overlapping features with fibrous dysplasia so that clinical and radiologic correlation is required in rendering a diagnosis.

- Complete bone maturation is seldom seen.
- Fibrous stroma may be densely cellular; mitotic figures are rare to absent.
- Secondary changes, including hemorrhage, inflammation, and giant cells, may be seen.
- Lesions with associated cementum are referred to as cementifying fibroma and those lesions with cementum and bone are referred to as cemento-ossifying fibroma:
 - Cementum is mineralized material covering the surface of roots of teeth.
 - There is no clinical relevance in distinguishing cementum from bone.
- Immunohistochemistry:
 - Reactivity for osteocalcin:
 - Weak in ossifying fibroma
 - Strong throughout calcified regions in fibrous dysplasia

- Cytogenetics and molecular genetics:
 - Guanine nucleotide-binding protein/ α -subunit (GNAS) mutational analysis by PCR reported to be:
 - Absent in ossifying fibromas, cemento-ossifying fibromas, and cemento-ossifying dysplasias:
 - Also reported to be absent in odontogenic myxomas
 - Present in fibrous dysplasia

Differential Diagnosis

- Primarily with fibrous dysplasia (see below and Table 6-1)
 - Differentiation of ossifying fibroma from fibrous dysplasia is important because the therapeutic rationale differs for these lesions.

Treatment and Prognosis

- Surgical excision is the preferred treatment:
 - Well-circumscribed nature of this lesion allows for relatively easy removal.
- Prognosis is excellent after complete excision.
- Recurrences are rare.

Peripheral Ossifying Fibroma

- Represents an oral mucosal or soft tissue (nonintraosseous) ossifying fibroma:
 - Similar to intraosseous (central) ossifying fibroma; also presumably arises from periodontal ligament
- Believed to represent a reactive process rather than a neoplastic proliferation
- More common in women than in men; most common in the second decade of life
- Unique to gingival mucosa:
 - Majority occurs anterior to molar region, equally affecting mandible and maxilla.
- Presents as firm, sessile to pedunculated mass measuring up to 1 cm in greatest dimension:
 - Overlying epithelium may be intact and smooth in appearance or ulcerated.
- Histology includes:
 - Unencapsulated cellular lesion composed of connective tissue, plump-appearing fibroblasts with large, round to oval vesicular nuclei and mineralized material, the latter including interlacing trabeculae of bone or osteoid, calcification, or spherules of cementum
 - Multinucleated giant cells associated with bone and calcified material may be present.
 - Chronic inflammatory cell infiltrate may be present along the periphery of the lesion.

- Complete surgical resection is the preferred treatment, often requiring excision of the lesion as well as the periodontal ligament and periosteum:
 - Tooth extraction is not usually required.
- Up to 20% of cases may recur.

Fibrous Dysplasia (Figs. 6-11 and 6-12)

Definition: Idiopathic nonneoplastic bone disease in which normal medullary bone is replaced by structurally weak fibro-osseous tissue.

- Three variants are identified: monostotic, polyostotic, polyostotic with endocrinopathy (McCune-Albright syndrome).

Monostotic Fibrous Dysplasia

- Only a single osseous site is involved.
- Represents greater than 75% to 80% of all cases
- Frequently occurs in older children and young adults
- Most commonly affects ribs, femur, and tibia
 - Involves head and neck bones in up to 25% of cases:
 - In head and neck most common sites of involvement include maxilla (zygomatic process) > mandible (region of premolar and molar teeth)

> frontal bone > ethmoid and sphenoid bones
> temporal bone

Polyostotic Fibrous Dysplasia

- Involvement of two or more bones
- Represents approximately 20% to 25% of all cases
- May be limited to a few bones in one anatomic region or may be diffuse, affecting virtually every bone in the skeleton
- In greater than half the cases osseous involvement includes the long bones of the extremities, pelvic bones, ribs, metacarpals, metatarsals, and the humerus:
 - Craniofacial or jaw regions are included in up to 50% of patients.

Polyostotic with Endocrinopathy or McCune-Albright Syndrome

- Triad includes:
 - Polyostotic fibrous dysplasia
 - Endocrine dysfunction:
 - Hyperthyroidism and/or sexual precocity, the latter predominantly identified in females
 - Cutaneous hyperpigmentation

Fig. 6-11. Fibrous dysplasia of the maxilla.

There is gross expansion of the maxilla. The lesion contains multiple consistencies including soft tissue, bone, and perhaps cartilage. **A**, Axial image with multiple punctate areas of mineralization (*arrow*). The low density may represent fibrous tissue or a cystic component. **B**, Coronal image shows small foci of calcifications (*arrowhead*) that may represent chondroid matrix. This makes differentiation from chondrosarcoma difficult. The lateral part of the abnormality (*arrow*) has a typical “ground glass” appearance. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 25-55, p 1506.)

Fig. 6-12. Fibrous dysplasia.

Histologically, fibrous dysplasia is characterized by proliferation of fibrous tissue and osseous components; the osseous component includes immature (woven) bone, in which the trabeculae form odd geometric patterns ("Chinese" characters) and typically lack osteoblastic rimming; the fibrous tissue component is nondescript without pattern and of variable cellularity.

- Least common variant representing approximately 1% to 3% of all cases

General Clinical Features

- Monostotic type:
 - No gender predilection or slightly more common in women
- Polyostotic type:
 - More common in women than men
- Regardless of type, majority of patients affected are under 30 years of age, although older individuals may be affected:
 - In monostotic type most common in second to third decades of life
 - In polyostotic type and McCune-Albright syndrome tend to occur in the first decade of life

- Craniofacial symptoms include:
 - Painless, asymmetric, nonmobile swelling associated with functional disturbances
 - Displacement or malocclusion of teeth, failure of tooth eruption in children
 - Headaches, proptosis, nasal obstruction, especially for sinonasal tract lesions
 - Hearing loss (conductive)
- Laboratory findings:
 - Serum calcium and phosphorous levels are normal; alkaline phosphatase may be elevated.
- May be associated with:
 - Oncogenic osteomalacia
 - Cholesteatoma
- Radiology:
 - Poorly defined expansile osseous lesion with a thin intact cortex
 - Predominantly fibrous lesions are radiolucent.
 - Predominantly osseous lesions are radiodense.
 - Equal admixture of fibrous and osseous components results in a ground glass appearance.
 - Usually no periosteal reaction is seen unless there is an associated fracture.
- Cause remains unknown:
 - No familial or hereditary origin
 - Cherubism is congenital form of fibrous dysplasia:
 - Autosomal dominant disease with variable expressivity
 - Characterized by lateral swelling of the jaws:
 - Bilateral symmetric involvement is almost pathognomonic.
 - Usually involves the mandible with the ramus always involved.
 - Patients have characteristic upturned appearance of the eyes, resulting in a cherubic expression.
- Rarely may be associated with soft tissue myxomas referred to as Mazabraud syndrome:
 - Defined as combination of one or more intramuscular myxomas and fibrous dysplasia of bone
 - Association is more common with polyostotic fibrous dysplasia and McCune-Albright syndrome
 - Myxomas tend to appear years (decades) after bone lesions
 - Soft tissue myxomas most common in the thigh (intramuscular)
 - Often multiple and tend to occur near to abnormal bones
 - These patients are at increased risk for malignant transformation:
 - Risk is greater than in those with fibrous dysplasia alone
 - Risk increases when patient has both McCune-Albright and Mazabraud syndromes

Pathology

Gross

- Tan-white to yellow, soft, rubbery, gritty, or firm tissue
- Thin cortex

Histology

- Fibrous tissue component is nondescript and of variable cellularity
- Osseous component includes:
 - Irregularly shaped trabeculae of osteoid and immature (woven) bone arising metaplastically from fibrous stroma
 - Poorly oriented with misshapen bony trabeculae, increased cellularity, and irregular margins and forms odd geometric patterns including C- or S-shaped configurations, so-called Chinese characters
 - Trabeculae typically lack osteoblastic rimming.
- Multinucleated giant cells, macrophages, increased vascularity, and calcification may be seen.
- Under polarized light bone appears woven rather than lamellar; however, lamellar bone can be seen in fibrous dysplasia, and its presence does not exclude the diagnosis.
- Immunohistochemistry:
 - Reactivity for osteocalcin:
 - Strong throughout calcified regions in fibrous dysplasia
 - Weak in ossifying fibroma
- Cytogenetics and molecular genetics:
 - Guanine nucleotide-binding protein/ α -subunit (GNAS) mutational analysis by PCR showed:
 - Presence in fibrous dysplasia
 - Absence in ossifying fibromas, cemento-ossifying fibromas, and cemento-ossifying dysplasias
 - Also reported to be absent in odontogenic myxomas

Differential Diagnosis

- Ossifying fibroma (see [Table 6-1](#)):
 - Gnathic fibro-osseous lesions (fibrous dysplasia and ossifying fibromas) may be histologically indistinguishable; therefore the diagnosis and differentiation rest on the clinical–radiologic–histopathologic correlation.
 - Differentiation of ossifying fibromas from fibrous dysplasia is important because the therapeutic rationale differs for these lesions.

Treatment and Prognosis

- Conservative surgical excision is the preferred treatment and is indicated only in cases with compromise of function, progression of deformity, pain,

associated pathologic fracture(s), or the development of a malignancy.

- Disease may stabilize at puberty and, in children, therapy should be delayed if possible until after puberty.
- Radiation treatment is not used because of the risk of inducing malignant change.
- Recurrence rates are low and death due to extension into vital structures rarely occurs.
- Malignant transformation:
 - Occurs in less than 1% of cases but is most feared complication
 - When it occurs is most often an osteosarcoma > chondrosarcoma > fibrosarcoma:
 - Also associated with angiosarcoma, Ewing sarcoma, and malignant mesenchymoma, including osteosarcomatous, chondrosarcomatous, and rhabdomyosarcomatous elements
 - Most common in craniofacial bones (maxilla and mandible) followed by femur and tibia
 - Peaks in third and fourth decades
 - May occur spontaneously or in patients treated by prior radiation
 - Identified more often in association with the monostotic type:
 - Risk increases when patient has both McCune-Albright and Mazabraud syndromes
 - Risk is greater than in those with fibrous dysplasia alone
 - Tends to occur years to decades after development of fibrous dysplasia
 - Treatment is similar to that of a primary malignant bone tumor.
 - Prognosis is poor with tendency to metastasize to lungs and short survival periods.

Giant Cell Tumor of the Head and Neck ([Figs. 6-13](#) and [6-14](#))

Definition: Benign but potentially aggressive primary tumor of bone composed of stromal mononuclear cells and osteoclast-like giant cells.

Synonym: Osteoclastoma

Clinical

- Most occur at ends (epiphyses) of long bones with distal femur the most common site followed by proximal tibia
- Rare in the head and neck:
 - Less than 2% of all giant cell tumors occur in head and neck.
 - Propensity to affect sphenoid, temporal, and ethmoid bones
- More common in women than in men; occur over a wide age range

Fig. 6-13. Giant cell tumor.

Contrast-enhanced CT scan (A) and axial T1-weighted (B) and T2-weighted (C) MR images demonstrate a large, septated destructive mass of the right mandible. The tumor is well defined and multiseptated. Multiple fluid levels are obvious, especially in C. (From Som P, Curtin H: *Head and neck imaging*, ed 4, St Louis, 2003, Mosby.)

- Symptoms vary per site of involvement:
 - Sphenoid and ethmoid bones
 - Headaches, diplopia, visual disturbances, proptosis
 - Middle ear, temporal bone, petrous bone:
 - Conductive hearing loss
 - Vertigo and sensorineural hearing loss
- Laboratory:
 - No abnormalities of serum calcium

- Radiology:
 - Lytic lesions with or without involvement/destruction of adjacent bones

Pathology

Histology

- Characterized by the presence of abundant multinucleated giant cells and stromal mononuclear cells
- Multinucleated giant cells:
 - Diffusely and evenly distributed, are large and have numerous nuclei (10 to 100)
 - Nuclei are round to oval with or without nucleoli and tend to cluster in the center of the giant cells.
 - Cause bony destruction
 - Are thought to be recruited from normal mononuclear stromal cells
- Mononuclear cell stromal component:
 - Plump, ovoid, or spindle-shaped
 - Nuclei similar to those seen in the giant cells
 - No cytologic atypia
- Variable associated thin-walled blood vessels:
 - Identification of intravascular tumor especially at the periphery of the tumor may be seen but has no clinical import.
- Mitoses are seen in the stromal mononuclear cells and may be abundant but atypical mitoses are not present:
 - Presence of atypical mitoses identified as an indicator of malignancy
- Additional findings may include the presence of foam cells, osteoid, and rarely chondroid:
 - Foam cells frequently present and in some case may be abundant
 - Reactive bone may be focal or abundant, usually in the form of seams of osteoid with prominent osteoblastic rimming.
 - Cartilage formation is uncommon, and presence of chondroid material should engender consideration of another lesion.
 - Secondary aneurysmal bone cysts are not uncommon:
 - May be present as microscopic cysts
- Absence of collagenized or fibroblastic background unless previously biopsied or traumatized
- Immunohistochemistry:
 - Multinucleated giant cells:
 - Express strong CD68 (KP1) staining (monocytic/histiocytic lineage) and vimentin staining
 - Smooth muscle actin negative
 - Exhibited an osteoclast phenotype expressing tartrate-resistant acid phosphatase and vitronectin receptor

Fig. 6-14. Giant cell tumor.

A and B, Histology is characterized by the presence of diffusely and relatively evenly distributed multinucleated giant cells. **C,** Multinucleated giant cells are large and have numerous nuclei that are round to oval with nucleoli with tendency to cluster in the center of the giant cells; around the giant cells is the mononuclear cell stromal component composed of plump, ovoid-appearing cells with nuclei similar in appearance to those seen in the giant cells. There is an absence of cytologic atypia. **D,** Mitotic figures (*arrow*) may be seen and in any given case may be numerous, but atypical mitotic figures should not be present.

- Mononuclear stromal cells:
 - p63 reactivity (strong nuclear staining)
 - Exhibited an osteoblast phenotype, expressing:
 - Alkaline phosphatase, and the receptor activator for nuclear factor kappa B ligand (RANKL), a factor that is essential for osteoclast formation
 - Also expressed osteoprotegerin (OPG), an inhibitor of osteoclastogenesis, and TNF-related apoptosis-inducing ligand (TRAIL), a receptor that binds OPG:
 - These findings indicate that the mononuclear and giant cell components of giant cell tumor have similar phenotypic features and that the accumulation of osteoclasts in these giant cell-rich tumors occurs by a receptor activator of nuclear factor kappa-B ligand (RANKL)-dependent process
 - RANKL expression by osteoblast-like mononuclear stromal cells in these tumors stimulates osteoclast formation and resorption accounting for the osteolysis associated with these giant cell-rich tumors
 - Inhibitors of osteoclast formation and activity are likely to be effective in controlling the osteolysis associated with GCTB and possibly other giant cell-rich lesions.
 - Identification of angiogenic factors, including vascular endothelial growth factor (VEGF) and basic fibroblastic growth factor (bFGF) in mononuclear cells and giant cells, may play a role in the process of osteoclastogenesis, potentially contributing to additional growth in these lesions.
- Cytogenetics and molecular genetics:
 - Telomeric associations (TAS) represent the most frequent chromosomal translocation.

- Telomeric associations on 11p and dicentric chromosomes
- Clonal abnormalities, such as del(17p), and losses of chromosomes 4, 13, and 18 and gains on chromosome 7
- Comparative genomic hybridization: chromosomal imbalances with gains on chromosomes 1p31-q44, 6q12-q23, and 12q15-q22

Differential Diagnosis

- Giant cell granuloma:
 - Share histologic similarities with giant cell tumor:
 - Divergent opinion whether giant cell tumor and giant cell granuloma represent spectrum of a single entity
 - Features in giant cell granuloma differing from giant cell tumor include:
 - Predilection to the gnathic bones, especially the mandible
 - Overall fewer numbers of giant cells with less even distribution of the giant cells
 - Frequent areas of hemorrhage and tendency for giant cells to cluster in areas of hemorrhage, as well as in proximity to vascular spaces
 - Greater amount of stromal collagenization
- Brown tumor of hyperparathyroidism:
 - Absence of abnormalities of serum calcium in giant cell tumor assists in differentiating these lesions.
- Chondroblastoma

Treatment and Prognosis

- Surgical excision (i.e., curettage) is the preferred treatment:
 - Treatment recommendation is based on the more common giant cell tumors of long bones.
 - In long bones recurrence rates vary from 20% to 50% after surgical curettage.
- Radiation is not recommended because:
 - These tumors are not felt to be radiosensitive.
 - There is believed to be increased risk of malignant transformation after radiation treatment.
- Medical therapies include diphosphonates and denosumab (RANKL inhibitors):
 - May be used in patients with untreatable disease, including refractory, recurrent, or metastatic giant cell tumor
- Rarely (less than 10%) morphologically benign giant cell tumors may metastasize:
 - May be referred to as benign metastasizing giant cell tumor
 - No reliable predictors of which lesions may metastasize
 - Metastasis may be solitary or multiple.
 - Metastatic disease most often to lungs; less often to lymph nodes and other visceral sites

- If solitary surgical resection is achievable (metastasectomy), prognosis is good.
- Rarely, more diffuse metastatic disease occurs and may result in death.
- Malignant transformation of giant cell tumors is uncommon, representing presence of histologically benign giant cell tumor in association with sarcomatous component:
 - Malignant giant cell tumors, primary and secondary:
 - Primary malignant giant cell tumor represents a de novo malignancy (i.e., at presentation).
 - Secondary malignant giant cell tumor represents malignant transformation of a previous tissue-verified benign giant cell tumor:
 - Most occur secondary to radiation treatment.
 - Could be considered postirradiation sarcoma
 - For primary and secondary malignant giant cell tumors, malignancy includes osteosarcoma, undifferentiated pleomorphic sarcoma, and fibrosarcoma.
 - Metastatic disease is most often to the lungs.
 - Poor prognosis with greater mortality associated with secondary as compared with primary malignant giant cell tumor
 - Rare malignant giant cell tumor of the sphenoid arising in setting of Paget disease.

Giant Cell Tumor of Soft Tissue (Osteoclastoma of Soft Tissue)

- Primary soft tissue neoplasm that is clinically and histologically similar to giant cell tumor of bone
- Majority occurs in upper and lower extremities but approximately 7% may occur in soft tissues of the head and neck
- Histology and immunoreactivity similar to that of giant cell tumor of bone
- Complete surgical resection is the preferred treatment.
- May locally recur in up to 12% of cases (often a function of inadequate excision)
- Rarely metastasizes

Osteoblastoma (Figs. 6-15 and 6-16)

Definition: Benign bone-forming neoplasm characterized by osteoblastic rimming of woven bony trabeculae (histologically similar to osteoid osteoma) but with potential for progressive/aggressive growth.

Synonym: Giant osteoid osteoma

Clinical

- Represent approximately 1% to 4% of all benign tumors of bone

Fig. 6-15. Osteoblastoma.

Coronal CT scan shows a bone density lesion in the right frontal and ethmoid bones. The bone is expanded, and the cortices are intact. Part of the lesion has a “ground glass” appearance; however, the lateral portion of the mass has very dense bone cap. This patient had a benign osteoblastoma. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 4-184, p 344.)

- Most common site of occurrence is in the vertebra:
 - Uncommon tumor of head and neck
 - In head and neck occurs most commonly in gnathic (jaw) bones:
 - More common in the mandible (body) than maxilla
 - Less common sites of occurrence include the cervical vertebrae, skull, sinonasal tract, and middle ear/temporal bone.
- More common in men than in women; overwhelming majority of cases (greater than 90%) occur in patients under 30 years of age
- Presentation is usually that of localized pain to involved site:
 - Unlike osteoid osteoma, pain is not nocturnal and aspirin does not typically assist in resolving the pain.
 - In addition to pain, other symptoms related to site of occurrence may include:
 - Jaws: swelling, loosening of teeth
 - Sinonasal tract: epistaxis, nasal obstruction
 - Middle ear/temporal bone: conductive hearing loss
- Radiology:
 - Well-defined or sharply circumscribed to poorly defined radiolucent/radiopaque lesion with variable mineralization:
 - Depending on the degree of mineralization may appear:
 - Predominantly lytic
 - Predominantly sclerotic
 - Mixed lytic and sclerotic

- Expansion of bone with cortical erosion and extension into adjacent soft tissue may be identified
- Usually measure more than 2 cm but rarely larger than 10 cm
- Absence of a nidus as seen in osteoid osteoma
- In gnathic bones may be intimately associated with roots of teeth
- Significant percentage of cases may radiographically show features similar to those identified in osteosarcoma.

Pathology

Gross

- Intact lesions are rarely seen by the pathologist, because curettage is the usual means of surgical treatment.
- Intact lesions are:
 - Usually well circumscribed with a hemorrhagic appearance and granular to somewhat gritty texture, depending on the degree of calcification
 - Older lesions may be more heavily calcified, resembling cancellous bone.
 - In all skeletal locations range in size from 1.5 cm to 10 cm in greatest dimension
 - Often lack the sclerotic rim, which is so prominent in osteoid osteomas

Histology

- Well-circumscribed/sharply demarcated lesion composed of intricate complex (anastomosing) bony trabeculae in loose fibrovascular stroma:
 - Trabeculae may connect with cortical bone at periphery of the lesion, suggesting maturation
 - Bony trabeculae are lined by a single layer of plump osteoblasts, which may have small bland nuclei or may have enlarged nuclei with prominent nucleoli:
 - Scattered typical mitotic figures may be identified in osteoblastic cells.
 - May lack mineralization or may be rather heavily calcified
 - Lace-like osteoid may be present in small percentage of cases
- Intertrabecular spaces contain a richly vascularized loose fibroblastic stroma.
- Chondroid areas are uncommon but may be seen focally.
- Rarely large atypical but degenerated-appearing hyperchromatic nuclei may be seen.

Aggressive Osteoblastoma

- Designation ascribed to those osteoblastomas with atypical features suggestive of malignancy, including:
 - Increase in epithelioid-appearing osteoblasts
 - Increased mitotic figures

Fig. 6-16. Osteoblastoma.

A, The interface between the tumor (*right*) and adjacent host bone (*left*) is rather well demarcated, contrasting with the destructive nature typically seen in osteosarcomas. **B**, Complex of bony trabeculae lacking mineralization and lined by a single layer of osteoblasts; intertrabecular space is vascularized and composed of loose fibroblastic stroma. **C**, Osteoblasts have an epithelioid appearance with low nuclear-to-cytoplasmic ratio. **D**, Lace-like pattern of osteoid suggesting a possible diagnosis of osteosarcoma but the cells lack cytologic atypia.

- Sheetlike or trabecular areas of osteoid
- Osteoclastic activity
- Absence of radiographic distinctive findings
- Metastatic disease and/or death not seen in the lesions
- Validity of existence of aggressive osteoblastoma questioned

Malignant Osteoblastoma

- Another entity whose validity as a distinct lesion with reproducible features has been questioned:
 - Designation used for lesion showing borderline features between osteoblastoma and osteosarcoma, including:
 - Cellular pleomorphism of osteoblasts
 - Large number of giant cells

- Speculated blue bone similar to that found in osteosarcoma
- May recur but metastatic disease not reported

Differential Diagnosis

- Osteoid osteoma:
 - Benign bone forming tumor with limited growth potential
 - Represents approximately 14% of all benign bone tumors
 - More common in men than in women; most common in the first to third decades of life
 - Majority occurs in femur and tibia
 - Rare in head and neck sites, where most common sites of occurrence include mandible and cervical vertebrae

- Pain, especially occurring at night (nocturnal pain), is most common presenting complaint; pain typically responds (i.e., pain relief) to non-steroidal anti-inflammatory drugs.
- Radiology:
 - Circumscribed dense cortical radiolucency surrounding marked sclerosis (nidus)
- Usually measures 1 cm or less
- Essential identical histology to osteoblastoma:
 - Exception is presence in osteoid osteoma of a nidus representing interconnecting mass of osteoid and immature (woven) bony trabeculae of variable length and thickness rimmed by osteoblasts
 - Because of shared histologic features (except for the nidus), differentiation may not be achievable in curetted material, thereby requiring radiographs to assist in differentiating osteoid osteoma from osteoblastoma.
- Complete surgical excision or ablation of the nidus (en bloc) is curative:
 - Depending on the site of occurrence may require multiple procedures
 - Medical management (nonsteroidal anti-inflammatory drugs) may be an option if surgical treatment is contraindicated.
- Aneurysmal bone cyst
- Fibrous dysplasia
- Giant cell tumor
- Odontogenic lesions/neoplasms:
 - Cementoblastoma, cemento-ossifying fibroma, cemento-osseous dysplasia
- Osteosarcoma:
 - Features in osteoblastoma that assist in excluding osteosarcoma include:
 - Sharp circumscription with no permeation or entrapment of surrounding host bone
 - Bony trabeculae embedded in loose connective tissue; lining of trabeculae by a single layer of osteoblasts
 - Features in osteosarcoma that contrast to those of osteoblastoma include:
 - Greater nuclear pleomorphism and hyperchromasia
 - Greater number of mitoses with atypical mitotic figures
 - More compact stromal component
 - Penetration of neoplastic cells between existing bone/bony trabeculae
 - Presence of sheets of osteoblasts without osteoid production

Treatment and Prognosis

- Conservative but complete surgical resection by curettage or local excision is the preferred treatment and is curative in majority of cases.
- Recurrent tumor is uncommon.
- Features potentially associated with aggressive behavior include:
 - Location of lesion:
 - Tumors of the central neuroaxis associated with increased morbidity and mortality
 - Presence of secondary aneurysmal bone cyst component:
 - Associated with more destructive behavior
 - Local control of disease:
 - Ability to completely resect tumor associated with excellent long-term prognosis
 - Histology alone is not predictive of aggressive behavior.
- Metastatic disease rarely, if ever, occurs.

BENIGN ODONTOGENIC NEOPLASMS

- Odontogenic tumors represent a broad group of relatively rare heterogeneous neoplasms.
- The full spectrum of odontogenic neoplasms is beyond the scope of this text.
- This section focuses on some of the more common odontogenic neoplasms with which the surgical pathologist may be confronted in daily practice.

Ameloblastoma

(Figs. 6-17 through 6-19)

Definition: Slow-growing, locally aggressive epithelial odontogenic jaw tumor recapitulating enamel organ development during tooth crown formation with a high propensity for recurrence:

- Thought to arise from reduced enamel epithelium of the dental follicle, remnants of odontogenic epithelium, lining of odontogenic cysts, or basal cells of the overlying oral (alveolar) mucosa
- May develop from an odontogenic cyst (e.g., dentigerous cyst, odontogenic keratocyst) or develop in association with another type of odontogenic neoplasm (e.g., adenomatoid odontogenic tumor, others) referred to as hybrid tumor.
- Based on various clinical and pathologic features, ameloblastomas can be divided into four categories, including:
 - Solid/multicystic:
 - Are intraosseous
 - Unicystic:
 - Are intraosseous
 - Desmoplastic:
 - Are intraosseous
 - Peripheral:
 - Arise in extraosseous (mucosal) locations

Fig. 6-17. Ameloblastoma.

Ameloblastoma, solid/multilocular type in a 25-year-old man. **A**, Pantomogram shows a large, multilocular, expansile lesion in the right side of the mandible (*arrowheads*). There is no root resorption of adjacent teeth. A cystic lesion is suspected. **B**, Coronal CT shows the expansile multilocular lesion, with bulging of the bony cortex without perforation. **C**, Coronal T1-weighted MR image reveals a lesion of homogeneously low signal intensity in the mandible (*arrowheads*). **D**, Enhanced coronal MR image shows the markedly enhanced solid lesion in the mandible. The mandibular canal can be seen under the solid mass (*arrow*). (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 25-22, p 1484 [panels A through D]).

Fig. 6-18. Ameloblastoma, follicular (solid and cystic) variant.

A, Expansile lesion of the right mandible with displacement of teeth. **B** and **C**, Solid and cystic tumor composed of proliferating nests or islands of odontogenic (ameloblastic) epithelium including central area of loosely arranged cells similar to the stellate reticulum of the enamel organ and a peripheral area of palisading columnar or cuboidal cells with hyperchromatic small nuclei oriented away from the basement membrane (reverse polarity).

Ameloblastoma, Solid/Multicystic Type

Clinical

- Second most common odontogenic tumor (odontoma is considered the most common odontogenic tumor)
- Most common type of ameloblastoma, representing greater than 80% of all cases
- No gender predilection; occurs over a wide age range but most commonly occurs in the fourth to sixth decades of life; rare under 20 years of age
- Greater than 80% involve the mandible with predilection for the posterior mandibular region (molar-ramus area > premolar area > symphysis); often associated with unerupted third molar teeth:
 - Predilection to the molar-ramus area is thought to be the result of:
 - Aberrant tooth germs often found in this region
 - Posterior end of the dental lamina proliferates continuously.

- Maxillary ameloblastomas occur primarily in the posterior (molar) region
- May occur as a primary sinonasal tract neoplasm; see Section 1, Sinonasal Tract, for detailed discussion.
- Most common clinical presentation is a painless swelling of the affected area; pain or paresthesia is rare
- Radiology:
 - Unilocular or multilocular radiolucent lesion resembling cysts with a honeycomb appearance and scalloped borders
 - Extensive thinning of cortical bone can often be seen.
 - Desmoplastic type may present as mixed radiolucent/radio-opaque lesions

Pathology

Gross

- Predominantly solid but microcyst may be identified

Fig. 6-19. Histology of ameloblastoma.

Histologic variants of ameloblastoma include (A) plexiform, composed of long columns (trabeculae) of columnar epithelial cells with minimal to no evidence of central stellate reticulum although around the columns stellate reticulum is readily identified; (B) acanthomatous, characterized by squamous metaplasia in central areas replacing the stellate reticulum; (C) granular cell, composed of varying cells with prominent granular, eosinophilic-appearing cytoplasm; there is retention of peripheral columnar cells (*arrowhead*). D, Basal cell type is the least common variant and is comprised of small, ovoid, basaloid cells with scant cytoplasm in central areas replacing typical stellate reticulum and retention of peripheral columnar cells with reverse polarity of hyperchromatic nuclei (*arrow*). E, Plexiform and granular cell characterized by trabeculae comprised of granular cells. Any given example of ameloblastoma may include multiple histologic types.

Histology

- Several histologic variants may be seen:
 - Histologic subtypes can be found independently or admixed within the same tumor.
- Follicular (solid and cystic) variant:
 - Most common histologic variant
 - Variably sized epithelial islands composed of central loosely arranged cellular areas identical to stellate reticulum of enamel organ with squamous cells, basal cells, or granular cells surrounded by columnar epithelial cells with clear to vacuolated cytoplasm and hyperchromatic (basaloid) nuclei aligned at the periphery away from the basement membrane referred to as reverse polarity of the nuclei
 - Absence of significant nuclear pleomorphism and increased mitotic activity
 - Microcyst formation commonly present in this histologic subtype
 - Mucocytes may rarely be found.
 - Desmoplastic:
 - Considered a variant of follicular ameloblastoma characterized by presence of a markedly desmoplastic stroma
- Plexiform variant:
 - Second most common histologic variant
 - Composed of long, anastomosing double columns and sheets of cuboidal or columnar epithelial cells with reverse polarity of the peripheral located nuclei with minimal to no evidence of central stellate reticulum
- Acanthomatous variant:
 - Identical to follicular type but characterized by presence of extensive squamous metaplasia in central areas replacing typical stellate reticulum
 - Squamous metaplasia includes keratin pearl formation and individual cell keratinization:
 - Absence of significant nuclear pleomorphism or mitotic activity
 - Retention of peripheral columnar cells with reverse polarity of hyperchromatic nuclei
 - Keratoameloblastoma:
 - Term for ameloblastomas with extensive keratinization of central areas
 - Includes surface parakeratin
 - May show papillary growth (papilliferous keratoameloblastoma)
- Granular cell variant:
 - Composed of varying numbers of cells with prominent granular, eosinophilic-appearing cytoplasm
 - Retention of peripheral columnar cells with reverse polarity of hyperchromatic nuclei

- May show anastomosing trabeculae or cords
- Basal cell variant:
 - Least common variant
 - Composed of small, ovoid, basaloid cells with scant cytoplasm in central areas replacing typical stellate reticulum
 - Retention of peripheral columnar cells with reverse polarity of hyperchromatic nuclei
 - May be histologic type seen in association with peripheral (extraosseous) ameloblastomas
- Additional cell types that can be seen including mucous cells, clear cells, and cells with melanin pigment
- Infiltrative growth may be seen with any histologic variant, including infiltration of bone.
- Special stains including histochemistry and immunohistochemistry are of limited utility in the diagnosis.
- No specific cytogenetic or molecular genetic findings

Differential Diagnosis

- Dentigerous cyst: see earlier in section
- Odontogenic keratocyst: see later in section
- Ameloblastic fibroma
- Squamous odontogenic tumor:
 - Rare benign odontogenic epithelial neoplasm thought to arise from epithelial rests of Malassez of the periodontal membrane
 - Most common in third to fourth decades of life
 - Occur most often in the anterior maxilla or posterior mandible
 - Radiology: well-demarcated radiolucent lesion with sclerotic, osseous border
 - Histologic features include:
 - Irregular-shaped islands of bland-appearing mature squamous epithelium without nuclear pleomorphism, nuclear hyperchromasia, increased mitotic activity, or dyskeratosis
 - Flattened peripheral cells with smoothly contoured connective tissue interface
 - Absence of stellate reticulum and peripheral nuclear palisading with reverse polarity:
 - Assists in differentiating from acanthomatous variant of ameloblastoma
 - Cystic change may be present.
 - Abundant fibrous stroma
 - Epithelial islands may contain spherical eosinophilic hyaline material (reminiscent of Rushton bodies) that stain strongly with PAS
 - Absence of significant cytologic atypia allows for differentiation from intraosseous carcinoma or metastatic squamous cell carcinoma
 - Simple excision (enucleation or curettage) considered preferred treatment and is curative

Treatment and Prognosis

- Complete surgical resection is preferred treatment:
 - For small tumors that are well delineated, conservative but complete excision can be performed.
 - For larger tumors that have spread to adjacent tissues (e.g., bone, other) en bloc resection may be required to include at least 1 cm of normal tissue beyond radiographic margin.
- Surgical curettage not an acceptable form of therapy
- Considered radioresistant; chemotherapy has no proven efficacy.
- Recurrence is not uncommon and may lead to extensive local destruction with facial disfigurement or may pose life-threatening complications as a result of extension into vital structures.
- Metastases are rare and are generally related to long-standing tumors associated with multiple surgical procedures or radiation treatment.
- Prognosis for ameloblastomas depends on tumor size, extent of disease, and location of the tumor:
 - Mandibular ameloblastomas tend to be confined tumors, due to the inherently thick cortical mandibular bone
 - Maxillary ameloblastomas are more likely to demonstrate extension beyond the bone, due to the absence of a thick cortical bone and the intimate association with the sinonasal cavity.
- Malignant ameloblastoma:
 - Represents ameloblastomas with benign features yet metastasize
 - Diagnosis can be rendered only after identification of metastatic tumor:
 - Also referred to by designation metastasizing ameloblastoma
 - Rare occurrence
 - Lung followed by regional lymph nodes represent most common sites for metastases:
 - Other reported metastatic sites include bone, brain, kidney, intestine, and liver.
 - Interval between diagnosis of primary tumor and metastasis can be years
- Ameloblastic carcinoma (Figs. 6-20 and 6-21):
 - Represents rare malignant transformation of a benign ameloblastoma characterized by cytologically malignant epithelial cells with marked nuclear pleomorphism, increased nuclear-to-cytoplasmic ratio, increased mitotic activity, necrosis, and lymph-vascular invasion:
 - Predilection for the mandible
 - Presentation may include pain, swelling, trismus, and odynophagia
 - Treated by surgical resection

Fig. 6-20. Ameloblastic carcinomas of the mandible in 28-year-old woman.

A, Pantomogram shows a multilocular, expansile lesion in the mandible (arrows). **B**, Axial CT image reveals a multilocular, expansile lesion in the mandible with perforation of bony cortex in right side of the mandible. The mass contains central necrosis and invades masseter muscle, suggesting malignancy (arrows). (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 25-81, p 1520.)

- May metastasize to regional lymph nodes and distantly to lungs, bone, and liver
- Poor prognosis
- Ameloblastic fibrosarcoma (ameloblastic sarcoma) (Fig. 6-22):
 - Rare malignancy in which there is mixed epithelial-mesenchymal odontogenic neoplasm composed of a sarcomatous mesenchymal component arising:
 - De novo
 - From pre-existing odontogenic mixed neoplasm such as an ameloblastic fibroodontoma or ameloblastic fibroma
 - Histology includes foci of ameloblastoma most often in a follicular pattern surrounded

Fig. 6-21. Ameloblastic carcinoma.

Ameloblastic carcinoma includes the presence of histologically identifiable (benign) ameloblastoma (*top right*) transitioning to cytologically malignant area with features of squamous cell carcinoma characterized by presence of individual cell keratinization and intercellular bridges with nuclear pleomorphism, increased nuclear-to-cytoplasmic ratio, and increased mitotic activity.

by sarcomatous proliferation with fascicular to herringbone pattern composed of malignant spindle-shaped cells with marked nuclear pleomorphism, increased mitotic activity including atypical mitoses and necrosis

- Biomarker analysis showed alterations of p53 and c-KIT genes restricted to the sarcomatous component
- Treatment follows that for other sarcomas, including radical extirpation and chemotherapy.

Ameloblastoma, Unicystic Type

(Figs. 6-23 and 6-24)

Definition: Variant of conventional ameloblastoma in which there is a single, often large unilocular cyst lined by ameloblastomatous epithelium.

- May develop de novo
- May develop in a preexisting odontogenic cyst

Clinical

- From 5% to 15% of all ameloblastomas are of the unicystic type
- No gender predilection; tends to occur at a younger age than solid/multicystic ameloblastoma primarily in the second to third decades of life
- Greater than 90% involve the mandible, usually the posterior portion of the mandible.
- May be asymptomatic or present as a painless swelling of affected area

Fig. 6-22. Ameloblastic sarcoma.

The histology includes foci of ameloblastoma, follicular pattern, surrounded by sarcomatous proliferation composed of malignant spindle-shaped cells with nuclear pleomorphism, increased mitotic activity.

- Often associated with an impacted tooth, making it indistinguishable from a dentigerous cyst
- Radiology:
 - Well-delineated unilocular radiolucency
 - Occasionally may show demarcated, perilesional corticated rim
 - Radiolucency often associated with an unerupted tooth, making it indistinguishable from a dentigerous (follicular) cyst

Pathology

Gross

- Indistinguishable from other gnathic cysts

Histology

- Histology subdivided into luminal, intraluminal, and mural types

Fig. 6-23. Ameloblastoma, unicystic type.

A, Panoramic radiograph shows a large, unilocular, expansile lesion with an unerupted tooth in the right side of the mandible (*arrowheads*). There is root resorption of adjacent teeth (*arrow*). A cystic lesion is suspected. **B**, Axial CT shows an expansile unilocular lesion, with bulging of the bony cortex without perforation. **C**, Enhanced axial MR image shows a papillary projection (*arrowheads*) along the walls of the unilocular lesion. **D**, Axial T2-weighted MR image reveals the lesion to be of high signal intensity. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 25-27, p 1488.)

Fig. 6-24. Ameloblastoma, unicystic type.

A, Unicystic luminal type in which the epithelial lining shows palisaded cuboidal and columnar basal cells with reverse polarization. **B**, Intraluminal plexiform unicystic type (plexiform unicystic ameloblastoma) composed of interlacing strands (plexiform) of solid and squamoid-appearing ameloblastoma epithelium lacking reverse polarization.

Luminal Type (Intraepithelial Type)

- Cystic lesion composed of a fibrous tissue wall with the cyst lined by ameloblastomatous epithelium characterized by palisaded cuboidal to columnar basal cells with hyperchromatic nuclei, nuclear polarization, and subepithelial hyalinization

Intraluminal Type

- Similar to luminal type but with one or more nodules of ameloblastomatous epithelium projecting into the lumen
- In examples showing presence of a delicate connective tissue stroma in which interlacing strands of ameloblastomas epithelium are embedded the designation plexiform unicystic ameloblastoma is used:
 - Does not always have palisading columnar cells, nuclear hyperchromasia, and reverse polarization

- Central areas are predominantly solid and squamoid and not loose, resembling stellate reticulum.

Mural Type

- Nests or islands of typical ameloblastomatous epithelium (follicular or plexiform pattern) penetrate or infiltrate the connective tissue cyst wall.

Differential Diagnosis

- Dentigerous cyst

Treatment and Prognosis

- Luminal and intraluminal unicystic ameloblastomas can be treated by curettage or enucleation:
 - Given the presumptive clinical diagnosis of dentigerous cyst, curettage, or enucleation is often performed and only after histologic evaluation is the correct diagnosis rendered.
 - Recurrence rates after curettage or enucleation are low.
- For mural unicystic ameloblastomas, partial or complete jaw resection is recommended given the tendency of this lesion to penetrate bone, resulting in recurrent tumor if inadequately managed.
- Recurrence rates tend to be lower than those for intraosseous ameloblastoma, especially relative to luminal and intraluminal lesions:
 - Approximately 6% without mural involvement
 - Approximately 37% with mural involvement

Ameloblastoma, Desmoplastic Type (Figs. 6-25 and 6-26)

Definition: Ameloblastoma characterized by predominant fibrous connective tissue with irregularly distributed odontogenic epithelium.

Clinical

- From 3% to 13% of all ameloblastomas are of the desmoplastic type.
- No gender predilection, although some reports cite a female predilection; tends to occur over a wide age range from the third to seventh decades of life.
- Predilection for the anterior segment of the mandible and maxilla
- May be asymptomatic or present as a painless swelling of affected area
- Radiology:
 - Unilocular or multilocular combined radiolucent-radio-opaque lesion with poorly demarcated borders
 - Radiologic features may be suggestive of a fibro-osseous lesion.

Fig. 6-25. Ameloblastoma, desmoplastic type, in the mandible.

A, Panoramic radiograph shows a diffuse, mixed radiolucent–radiopaque lesion in the mandible (arrowheads). **B**, Axial CT shows a definite buccal expansile radiolucent–radiopaque lesion (arrowheads). (Courtesy Dr. T. Kurabayashi, Dept. of Dental Radiology, Tokyo Medical and Dental University, Tokyo. From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 25-29, p 1490.)

Pathology

Histology

- Stromal desmoplasia predominates in the form of fibrous connective tissue with abundant collagen of moderate cellularity.
- Follicle-like islands of odontogenic epithelium are irregularly distributed in the collagenized stroma:
 - Typically lack peripheral nuclear polarization
 - Hypercellular central area composed of spindle-shaped cells; also may include squamous cells
 - Microcysts lined by flattened spindle-shaped cells may be seen in centers of the odontogenic epithelial islands; microcysts may occasionally contain eosinophilic material.
- Metaplastic osteoid may be seen and on occasion may be prominent.

Fig. 6-26. Ameloblastoma, desmoplastic type.

Stromal desmoplasia predominates in the form of collagenized fibroconnective tissue in which there is identifiable irregularly distributed nests, strands, and islands of odontogenic epithelium, some lacking peripheral nuclear palisading and stellate reticulum polarization but other islands showing characteristic peripheral palisading nuclei with reverse polarity and central stellate reticulum.

- Absence of a capsule
- Invasion into adjacent bone can be identified.
- Hybrid lesions refer to the admixture in a given lesion of desmoplastic and classic follicular or plexiform ameloblastomas.
- Immunohistochemistry:
 - Collagen type IV immunoreactivity adjacent to tumor islands, a feature not seen in conventional ameloblastoma:
 - Presence of collagen type IV is indicative of de novo synthesis of extracellular matrix proteins
 - Expression of TGF- β , a feature not seen in conventional ameloblastoma

Differential Diagnosis

- Squamous odontogenic tumor (see above)

Treatment and Prognosis

- Similar treatment as solid/multicystic ameloblastoma, including complete resection of the tumor to include at least 1 cm of normal tissue beyond radiographic margin
- Recurrence rates difficult to determine, owing to limited information in the literature

Ameloblastoma, Peripheral Type

Definition: Extraosseous counterpart to intraosseous ameloblastoma.

Synonyms: Ameloblastoma of mucosal or gingival origin; soft tissue ameloblastoma

Clinical

- Represent less than 10% of all ameloblastomas
- More common in men than in women; occurs over a wide age range but most common in the fifth to seventh decades of life
- Involves gingival or alveolar mucosa of the mandible more often than the maxilla:
 - Mandibular involvement is most common in the canine-premolar region.
 - Maxilla involvement is most common in the tuberosity area.
 - May rarely occur in extragingival sites
- Presentation is painless mass or swelling
- Radiology:
 - Absence of intraosseous radiographic abnormality given its mucosal or soft tissue localization
- Proposed histogenesis is from odontogenic epithelial remnants in the gingival lamina propria or from the basal cell layer of gingival epithelium.

Pathology

Gross

- Sessile exophytic, soft to firm mass with smooth, pebbly, or papillary surface measuring from 0.3 to 6 cm in greatest dimension

Histology

- Histologically similar to intraosseous solid/multicystic ameloblastoma but localized to submucosa without osseous involvement.
- Absence of invasive/destructive growth

Differential Diagnosis

- Peripheral odontogenic fibroma
- Peripheral squamous odontogenic tumor
- Craniopharyngioma:
 - Histologic similarities exist between ameloblastoma and craniopharyngioma and rare occurrence of a (peripheral) ameloblastoma in the

nasopharynx, and rare occurrence of craniopharyngioma in infrasellar (e.g., nasopharyngeal) location may result in differential diagnostic difficulties.

- See Section 3, Pharynx, for complete discussion and illustrations.

Treatment and Prognosis

- Conservative surgical resection is the preferred treatment.
- Low recurrence rate
- Rare examples of malignant peripheral ameloblastomas reported

Odontogenic Keratocyst (OKC) or Keratocystic Odontogenic Tumor (KCOT) (Figs. 6-27 and 6-28)

Definition: Distinctive intraosseous, uni- or multicystic tumor of odontogenic epithelial origin with specific clinical behavior and histopathologic features, including potentially aggressive (infiltrative) growth and association with nevoid basal cell carcinoma syndrome.

Synonyms: Odontogenic keratocystoma; primordial cyst

- 2005 World Health Classification of odontogenic lesions:
 - Defines OKC as a neoplasm and recommends the use of the designation KCOT reflective of its neoplastic nature
 - Neoplastic nature supported by molecular evidence (see below)
 - Given the time-honored use of OKC, this designation is used in this section.

Fig. 6-27. Odontogenic keratocyst: a well-defined uniloculated cyst.

(From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 4-249A, p 380.)

Fig. 6-28. Odontogenic keratocyst.

A and **B**, Odontogenic keratocyst composed of relatively flat-appearing stratified squamous epithelium of 5 to 10 cell layers with surface keratinization including the presence of nuclei (parakeratosis), absence of rete ridges, basal epithelial cells with hyperchromatic nuclei, and nuclear palisading and characteristic corrugated (undulating or wavy) appearance. In **A** there is desquamated keratin (keratinaceous debris) within the cyst lumen as well as areas in which the epithelium appears separated from the connective tissue representing a common feature in odontogenic keratocysts. **C**, In the presence of inflammation (*upper left*) the characteristic features of the epithelial layer may be absent, although away from the inflammation the characteristic surface epithelium is present, including separation of the epithelium from the connective tissue; a satellite cyst is present within the cyst wall. **D**, Higher magnification of a satellite cyst. **E**, Epithelial hyaline bodies (Rushton bodies) can be seen characterized by hyalinized, eosinophilic, angulated, linear, or curved foci within the epithelium.

NOTE: Classification schemes for OKC have identified separate lesion types based on differences in biologic behavior and histomorphology, as well as associated syndromes into central (intraosseous) and peripheral (mucosal) with further subclassification based on the type of keratin layer, including:

- Central or intraosseous OKC:
 - Parakeratotic OKC
 - Orthokeratotic OKC
 - Combined (paraorthokeratotic) OKC
- Peripheral or mucosal OKC
- Clinical and histopathologic spectrum of OKC as defined above is limited to the central or intraosseous parakeratotic OKC, which is discussed here.

Clinical

- Represents more than 80% of odontogenic keratocysts and up to approximately 20% of odontogenic cysts
- Tends to be more common in men than in women; occurs over a wide age range but is most common in the second to third decades of life
- Affects the mandible more often than the maxilla (2:1):
 - In the mandible the most common location is the posterior aspect, specifically the third molar and ramus area
- May be solitary or multiple:
 - If multiple then possibly associated with nevoid basal cell carcinoma syndrome (see below)
- Approximately 50% of patients are asymptomatic.
- Associated symptoms include:
 - Swelling or (intraosseous) drainage of the involved site
 - Pain in the area over the angle of the mandible or preauricular region
 - Discomfort, abscess formation, fistulas, cellulitis, trismus, displacement of teeth, and neurologic involvement
 - Presence of neurologic symptoms depends on the location of the cyst.
 - Neurologic involvement may include paresthesia of the face, teeth, and/or mandible.
 - Expansion of the cyst may result in functional compromise of nearby structures (e.g., excretory duct of parotid gland).
 - Origin from the maxilla may result in nasal obstruction, involvement of the maxillary sinus.
- Laboratory studies:
 - Fluid content from the cyst is low in protein and shows keratocyst antigen.
 - Keratocyst antigen:
 - Soluble polypeptide
 - Present in keratocysts but absent in nonkeratinizing cysts
 - Identical antigenically with lactoferrin
- Radiology:
 - Radiographic features are highly suggestive of the diagnosis but not diagnostic.
 - Well-defined or demarcated, round or ovoid unilocular radiolucency with smooth to corticated margins:
 - >80% are unilocular
 - Periphery may have an ill-defined border with little or no periosteal reaction or cortical sclerosis
 - May be single or multiple
 - Large lesions may appear multilocular.
 - Adjacent tooth may be displaced.
 - An unerupted or impacted tooth may be part of the lesion in up to 40% of cases:
 - In such instances the radiologic appearance may suggest a diagnosis of dentigerous cyst
 - Resorption of roots of teeth adjacent to OKC is uncommon and, if present, may be more suggestive of dentigerous or radicular cyst.
- OKC are thought to originate from odontogenic epithelium and may be of two potential sources:
 - Dental lamina or its remnants
 - Extension of basal cells from the overlying oral epithelium
- Nevoid basal cell carcinoma syndrome:
 - Also referred to as Gorlin syndrome or Gorlin-Goltz syndrome
 - Autosomal dominant inherited disorder with high penetrance
 - Protein patched homolog 1 is a protein that is a member of the Patched family and in humans is encoded by *PTCH1* gene.
 - Caused by mutations in *PTCH* gene, a tumor suppressor gene mapped to chromosome 9q22.3-q31
 - Differences between OKC associated with the nevoid basal cell carcinoma syndrome from non-syndromic associated lesions include:
 - More common in females
 - Occurrence in the first decade of life
 - Greater tendency to be multiple cystic lesions
 - Preference to occur in the maxillary molar region
 - Major components of the syndrome include:
 - Multiple basal cell carcinomas:
 - Begin to appear at puberty or second and third decades of life
 - Most common on mid-face but often appear on skin not exposed to the sun
 - Histology similar to basal cell carcinoma not associated with the nevoid basal cell carcinoma syndrome
 - Multiple OKCs of the jaws
 - Skeletal anomalies are common, including rib and vertebral anomalies:

- Splaying and bifid ribs are most common, with fusion and partial absence being less common
- May be bilateral
- Other skeletal anomalies that can be seen with increased frequency include kyphoscoliosis, spina bifida occulta, and shortened metacarpals.
- Intracranial calcification (lamellar calcification of falx cerebri)
- Plantar and palmar pits:
 - Represent localized retardation of basal epithelial cell maturation
 - May give rise (along base) to basal cell carcinomas
- Characteristic facies with increased cranial circumference and frontal and temporoparietal bossing
- Numerous other abnormalities occur with varying frequency, including a variety of neoplasms:
 - Fibromas (ovarian, cardiac), medulloblastoma, meningioma, fetal rhabdomyoma

Pathology

Gross

- Cystic lesion with a thin, smooth lining, which is usually collapsed and folded and filled with straw-colored fluid and/or thick, cheesy-like material; infected cysts are filled with pus.

Histology

- Lining epithelium:
 - Composed of relatively flat-appearing stratified squamous epithelium of 5 to 10 cell layers with surface keratinization including the presence of nuclei (parakeratosis)
 - Absence of rete ridges
 - Characteristically shows a corrugated (undulating or wavy) appearance
 - Includes basal epithelial cells with hyperchromatic nuclei and nuclear palisading
 - Common feature is separation of the epithelial lining from underlying connective tissue
- Desquamated keratin (keratinaceous debris) can be found in the cyst lumens.
- Mitotic figures can be identified in particular within the suprabasilar layers.
- An inflammatory cell component is typically absent to mild:
 - In the presence of intense inflammation, characteristic features of the epithelial layers as described above may be absent.
 - Rete ridges may be present.
- Satellite cysts, including epithelial rests or small microcysts, may be present within the cyst wall.

- Variable epithelial dysplastic changes can be present but transformation to squamous cell carcinoma is considered rare.
- Ameloblastomatous transformation may be identified:
 - More common in lesions associated with the nevoid basal cell carcinoma syndrome
- Additional findings that may be present include:
 - Mineralization/dystrophic calcification of fibrous connective tissue cyst wall
 - Cholesterol accumulation in the form of cholesterol clefts
 - Epithelial hyaline bodies (Rushton bodies):
 - Hyalinized, eosinophilic, angulated, linear, or curved foci within epithelium
 - Melanin pigment and melanocytes
 - Respiratory type epithelium, mucocytes, and sebaceous glands
- Lesions associated with the nevoid basal cell carcinoma syndrome tend to show:
 - More satellite cysts
 - Solid islands of epithelial proliferation
 - Rests of odontogenic epithelium within the fibrous capsule
 - More commonly have foci of calcifications
- Immunohistochemistry:
 - High proliferating cell nuclear antigen (PCNA) and Ki67
 - Increase p53 positivity
 - p63 immunoreactivity (nuclear) present in most of the cystic epithelium except for the parakeratin
- Cytogenetics and molecular genetics:
 - Majority harbors chromosomal abnormalities (loss of heterozygosity), supporting supposition that OKCs are neoplastic
 - Harbor allelic loss at some of the same loci identified in squamous cell carcinoma, possibly explaining the rare occurrence of squamous cell carcinoma arising in OKC
 - Nevoid basal cell carcinoma syndrome is caused by mutations in *PTCH* gene, a tumor suppressor gene mapped to chromosome 9q22.3-q31.
 - Increasing evidence that the *PTCH* gene plays a role in the development of sporadic (not associated with nevoid basal cell carcinoma syndrome) lesions
 - Syndromic and nonsyndromic lesions show allelic loss of 9q22.
 - p53 and cyclin D1 overexpression more commonly seen in lesions associated with the nevoid basal cell carcinoma syndrome as compared with lesions not associated with this syndrome
 - HPV type 16 reported in a single case

Differential Diagnosis

- Dentigerous cyst
- Radicular cyst
- Orthokeratinized odontogenic cyst:
 - Clinically and histomorphologically different from OKC
 - Not associated with aggressive behavior
 - Not associated with nevoid basal cell carcinoma syndrome
 - Much less common than OKC
 - More common in men than women; tend to occur in young adults
 - Most commonly occur in the mandible, posterior areas; less common in the maxilla:
 - Most often involve unerupted mandibular third molar
 - Histologically, cyst lining composed of a relatively thin layer of noncorrugated stratified squamous epithelium lacking palisading basal layer and showing an orthokeratotic layer of varying thickness with prominent keratohyaline granules below the orthokeratotic surface:
 - In contrast to parakeratosis, orthokeratosis lacks the presence of nuclei within the keratinized surface.
 - Express lower levels of Ki67 and p53 as compared with OKC
 - Usually treated by enucleation and curettage
 - Recurrences are uncommon (approximately 2% recur).
- Ameloblastoma:
 - Overlapping features, including similar ages of occurrence, tendency to predilect to the posterior mandible, uni- and multilocular appearances, and tendency to recur, may present difficulties in diagnosis.
 - Light microscopic features are significantly different, allowing for distinguishing these tumor types.

Treatment and Prognosis

- Preferred treatment is complete surgical excision of the lesion in one piece:
 - Complete excision in one piece may prove difficult given the friable nature of the cyst wall.
 - Extent of surgery (i.e., conservative versus aggressive approach) predicated on size of the lesion, location of the lesion, presence or absence of extension into adjacent structures
- Potential to be locally destructive with invasion of adjacent soft tissues, as well as bone
- Tend to recur:
 - Reported frequency of recurrence varies from approximately 5% to greater than 60%.

- Recurrence may be a function of inadequate surgical removal of the entire cyst to include the cyst lining.
- Recurrence is more common in association with mandibular lesions, especially those located in the posterior body and ascending ramus.
- Multiple recurrences are not unusual.
- Recurrence usually occurs within 5 years of the initial diagnosis; however, recurrent lesions may occur years (10 or more years) after the initial resection:
 - For this reason long-term follow-up, including periodic radiologic imaging, advocated
- Other than the tendency to recur, the overall prognosis is very good.
- Occasional examples may not be controllable by surgery but behave in a progressive manner with destructive growth, including extension to the skull base.
- Rare examples associated with malignant transformation (squamous cell carcinoma)

Adenomatoid Odontogenic Tumor (AOT) (Figs. 6-29 and 6-30)

Definition: Benign epithelial odontogenic neoplasm, usually cystic, characterized by presence of whorled nodules of spindle cells, microcyst or duct-like spaces, and indolent behavior (i.e., slow growth).

Clinical

- Uncommon, representing from approximately 2% to 7% of all odontogenic tumors
- More common in females than in males; most (two thirds) occur in second decade; uncommon occurrence in individuals over 30 years of age
- Often asymptomatic, discovered during course in radiographic workup in individuals having problems with tooth eruption:
 - Larger lesions may cause painless expansion of bone.
- Two thirds of cases occur in maxilla and two thirds occur associated with crown of impacted tooth (follicular type), especially maxillary canines:
 - Intraosseous location unassociated with a tooth (extrafollicular type) may occur.
 - Peripheral (extraosseous) location occurs but is rare.
- Radiology:
 - Appear as unilocular radiolucency with well-circumscribed borders
 - Scattered fine radiopacities may be seen within radiolucent area:
 - Dependent on amount of mineralized tissue within the tumor
 - Described as “snowflakes”

Fig. 6-29. Adenomatoid odontogenic tumor.

A, Occlusal view shows a well-defined radiolucent lesion with curved margins, tooth displacement, and small internal calcifications in the maxilla (*arrowheads*). **B,** Axial CT shows the well-defined rounded lesion with the incorporated canine and tiny calcifications (*arrowheads*).
(From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 25-48, p 1501.)

- Origin unknown but most likely development is from residues of dental lamina and proliferation of odontogenic epithelium adjacent to reduced enamel epithelium of unerupted teeth

Pathology

Gross

- Well-circumscribed, usually encapsulated, often appearing cystic
- Majority measure from 1 to 3 cm

Histology

- Encapsulated proliferation of spindle-shaped as well as polygonal epithelial cells arranged in solid nodules, whorls and trabeculae, cords and strands in loose fibrovascular stroma:
 - Reticular growth may be seen.
 - Often with clear-appearing cytoplasm
- Cystic spaces referred to as duct-like found in varying numbers are lined by cuboidal to palisaded columnar cells:
 - Represents a characteristic features of this tumor:
 - Diastase-resistant, PAS-positive intraluminal eosinophilic material often seen
 - Some cystic structures show invagination of part of the wall, resulting in horseshoe-shaped structure with two layers of columnar cells separated by a zone of diastase-resistant, PAS-positive material.
 - Mitotic figures can be seen.
- Within nodules rosettes may be seen surrounding small eosinophilic amorphous diastase-resistant, PAS-positive material.
- Additional findings may include:
 - Extracellular calcified material often with concentric laminated rings or annular appearance may be seen adjacent to spindle-shaped and/or columnar cells
 - Eosinophilic, hyalinized dentinoid material often with entrapped epithelium seen in many cases, which may in part be calcified (dystrophic calcification)
 - Melanin pigment
- A common finding in limited areas of most cases are foci with histologic similarity to calcifying epithelial odontogenic tumor (CEOT).
- Histochemistry:
 - Congo red staining may show focal presence of apple green birefringence indicative of amyloid
- Immunohistochemistry:
 - Epithelial cells immunoreactive for variety of cytokeratins, including CK5, 8, 14, 17, 19
 - Low proliferation indices by Ki67 staining

Treatment and Prognosis

- Conservative but complete surgical excision is curative.
- Recurrence rates of approximately 2% reported

Calcifying Epithelial Odontogenic Tumor (CEOT) (Figs. 6-31 and 6-32)

Definition: Benign slow-growing but locally invasive odontogenic neoplasm characterized by sheets and islands of eosinophilic hyperchromatic pleomorphic cells with foci of mineralization and eosinophilic amorphous material that stains with amyloid markers.

Fig. 6-30. Adenomatoid odontogenic tumor.

A, Intracystic circumscribed to encapsulated cellular proliferation with nodular growth and sharp demarcation from the adjacent connective tissue. **B,** Gland-like or duct-like spaces lined by cuboidal to palisaded columnar cells represent a characteristic features. **C** and **D,** Solid nodules of spindle-shaped cells with whorled or swirling appearance without identifiable duct-like spaces. **E,** Extracellular calcified material with concentric laminated rings or annular appearance may be seen. **F,** Dystrophic calcification appearing as eosinophilic, hyalinized dentinoid material often with entrapped epithelium can be seen in many cases.

Fig. 6-31. Calcifying epithelial odontogenic tumor (Pindborg tumor).

Axial CT (bone window setting) shows marked expansion of the right mandible with loss of bone in the lateral cortex. Multiple calcific densities are noted within the lesion. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 25-30, p 1490.)

Synonyms: Pindborg tumor; calcifying odontogenic tumor

Clinical

- Rare tumor accounting for less than 2% of all odontogenic tumors
- No gender predilection; most common in the third to fifth decades of life
- May be intraosseous or extraosseous
 - Intraosseous:
 - Represents majority of cases
 - Occurs more often in the mandible than maxilla (2:1)
 - Usually occurs in molar-premolar region
 - 60% associated with unerupted tooth
 - Extraosseous:
 - 5% to 6% of cases are extraosseous.
 - Predilects to anterior segment of jaws
- Presentation is usually that of a slowly enlarging expansile painless lesion within posterior portion of affected jaw
- Approximately 60% associated with unerupted tooth, most often mandibular third molar
- Radiology:
 - Most appear as mixed radiolucent-radiopaque lesions but may show wide variation in appearance:
 - Well circumscribed to poorly demarcated
 - Unilocular or multilocular

- Radiolucent to combined radiolucent-radiopaque with multilocular appearance
- No known cause

Pathology

Gross

- Firm lesion that on cut section is solid with various amounts of calcification
- Minute cystic spaces may be present but prominent cystic change not present although rare cystic variant reported

Histology

Intraosseous CEOT

- Unencapsulated lesion with:
 - Irregular sheets and islands consisting of polyhedral epithelial cells with abundant eosinophilic cytoplasm, round to polygonal nuclei with hyperchromasia and pleomorphism, sharply defined cell borders, and well-developed intercellular bridges
- Other cell types seen in CEOT may include:
 - Cells with clear-appearing cytoplasm (clear cell variant of CEOT):
 - Clear cells contain glycogen (intracytoplasmic diastase-sensitive, PAS-positive).
 - May be dominant cell type raising consideration of an alternative diagnosis such as clear cell odontogenic carcinoma
 - Langerhans cells (Langerhans cell variant of CEOT):
 - These cells are immunoreactive for S100 protein and CD1a
 - Langerhans cells may be seen in “conventional” CEOT but occur in significantly increased numbers in so-called Langerhans cell variant of CEOT
 - Treatment and prognosis similar to conventional CEOT
- Mitotic figures may be seen but generally are few in number.
- Within sheets of lesional cells are various amounts of eosinophilic homogeneous material:
 - Mostly extracellular but may be intracellular swelling cells with eccentric displacement of disintegrated nuclei and loss of cell integrity
 - With increasing calcification, spherules with basophilic concentric laminations are formed.
 - May be present extensively in connective tissue away from tumor islands
 - Stain with Congo red (apple green birefringence) indicative of amyloid
- In minority of cases, foci with histologic features of adenomatoid odontogenic tumor may be present

Fig. 6-32. Calcifying epithelial odontogenic tumor.

A, Unencapsulated lesion composed of irregular sheets and islands of tumor with associated calcifications and acellular hyalinized material. **B,** Tumor is composed of polyhedral epithelial cells with abundant eosinophilic cytoplasm, round to polygonal nuclei with hyperchromasia and pleomorphism, sharply defined cell borders, and well developed intercellular bridges. **C,** Cells with clear appearing cytoplasm may be present and may be the dominant cell type representing the clear cell variant of CEOT. **D,** Extracellular eosinophilic homogeneous material that showed apple green birefringence by Congo red staining (not shown) and spherules with basophilic concentric laminations (psammoma bodies) may be identified. (Slide courtesy Mary Richardson, MD, DDS.)

- Immunohistochemistry:
 - Reactive for cytokeratins, EMA, p63, vimentin
 - Staining for purported myoepithelial-related markers including calponin and GFAP reported
 - Negative for S100 protein and smooth muscle actin

Extraosseous CEOT

- Histologically similar to intraosseous CEOT but:
 - Tumor cells tend to form strands and islands rather than large sheets.
 - Amount of calcified material may be minimal or absent.

Treatment and Prognosis

- Conservative surgical resection is preferred treatment.
- Recurrence rates range from 10% to 14%:
 - Long-term follow-up is required, in particular when conservative surgery is performed.
- Malignant calcifying odontogenic tumor:
 - Rare tumor
 - Histologically characterized by prominent nuclear pleomorphism, increased mitotic activity, increased proliferation rate, and lymph-vascular invasion.
 - Loss of p53 transcriptional activity

Calcifying Cystic Odontogenic Tumor (CCOT) (Figs. 6.33-6.34)

Definition: Benign cystic neoplasm of odontogenic origin characterized by ameloblastoma-like epithelium with eosinophilic ghost cells and calcifications.

Synonyms: Gorlin tumor, Gorlin cyst, Calcifying odontogenic cyst, odontogenic ghost cell tumor, dentinogenic ghost cell tumor

Fig. 6-33. Calcifying cystic odontogenic tumor.

A, Occlusal radiograph shows a unilocular lesion (arrowheads) with odontoma (arrow) in the right side of the maxilla. Calcified tissue can be observed adjacent to the odontoma. **B,** Pantomogram shows a pericoronal calcifying odontogenic cyst (arrowheads) with tiny calcifications. Root resorption can be observed at the left side of the milk tooth (arrow). (From Som & Curtin: *Head and Neck Imaging*, ed 5. Philadelphia: Elsevier, Figures 25-36 and 25-37.)

- World Health Organization classifies CCOT as a benign odontogenic neoplasm
- Various classification schemes suggested for CCOT including:
 - Benign cyst versus neoplasm
 - Cystic versus solid
 - Central (intraosseous) versus peripheral (extraosseous)
 - Odontogenic neoplastic variants
- CCOT may be associated with a variety of odontogenic neoplasms (hybrid tumors) referred to as neoplastic associated variants including:
 - Odontoma (most common)
 - Ameloblastoma
 - Solid/multicystic
 - Unicystic
 - Adenomatoid odontogenic tumor
 - Ameloblastic fibroma
 - Ameloblastic fibro-odontoma
 - Odonto-ameloblastoma
 - Odontogenic-fibromyxoma

Clinical

- Rare tumor accounting for less than 2% of all odontogenic tumors
- No gender predilection; wide age range from first to tenth decade of life, with peak incidence in second and third decades:
 - Lesions in young adults often associated with odontomas
- Usually asymptomatic unless secondarily inflamed
- Circumscribed, smooth surface mass measuring up to 4 cm in greatest dimension
- May be intraosseous or extraosseous
 - **Intraosseous:**
 - Equal distribution between maxilla and mandible
 - Most found in incisor-cuspid area (anterior portion of jaws)
 - Less commonly involve posterior portion of jaws
 - Present as painless swelling
 - **Extraosseous:**
 - Most found in incisor-cuspid area (anterior portion of jaws)
 - Appear as circumscribed, elevated, smooth surface mass
- Radiology:
 - Cystic unilocular or multilocular radiolucency with discrete well-defined margins containing scattered calcifications that may produce a “salt and pepper like” appearance
 - Displacement of teeth or root resorption occasionally seen

Fig. 6-34. Calcifying cystic odontogenic tumor.

A, Cystic odontogenic epithelial proliferation with ghost cells and calcifications. **B** and **C**, Loosely arranged epithelium of variable thickness with stellate cells, cuboidal to columnar-appearing basal cells with nuclear palisading and numerous eosinophilic ghost cells characterized by the loss of nuclei with preservation of cell outline. **D**, Ghost cells with dystrophic mineralization (calcification) surrounded by dentinoid. **E**, CCOTs may be associated with other odontogenic neoplasms (hybrid tumors), the most common being odontoma, as seen in this image characterized by the presence of enamel matrix, cementum, and pulp (*top*). Foci of CCOT including ghost cells are present adjacent to the odontoma (*arrowheads*). **F** and **G**, Ghost cell odontogenic carcinoma characterized by a solid proliferation of hyperchromatic and pleomorphic epithelial cells with increased mitotic activity and associated/admixed islands of ghost cells. This tumor occurred in a 10-year-old who had malignant transformation of a CCOT.

Fig. 6-34, cont'd

- Associated unerupted tooth seen in approximately one third of cases
- May be associated with odontoma, latter appearing as opaque component
- Radiologic appearance similar to that of adenomatoid odontogenic tumor and calcifying epithelial odontogenic tumor
- Extraosseous lesions may show saucerization and may occasionally displace adjacent teeth
- No known etiology

Pathology

Histology (for both intraosseous and extraosseous CCOT)

- Cystic, multicystic, or solid cellular proliferation comprised of an epithelial lining that includes:
 - Loosely arranged epithelium of 4 to 10 cells in thickness resembling stellate reticulum (stellate cells) of ameloblastoma
 - Basal cells that may be cuboidal or columnar with nuclear palisading resembling ameloblasts but histologic findings reaching criteria of ameloblastoma not typically identified
 - Eosinophilic material representing so-called **ghost cells** characterized by loss of nuclei with preservation of cell outline
 - May fuse to form large sheets of amorphous, acellular material
 - Similar to ghost cells seen in pilomatixoma (calcifying epithelioma of Malherbe) and craniopharyngioma
 - Mechanisms involved in formation of ghost cells are unknown

- Dystrophic mineralization (calcification) within ghost cells commonly present
- Foci of eosinophilic matrix material representing dysplastic dentin (dentinoid) or cementum may be present adjacent to epithelial component:
 - May result from inductive effect on adjacent mesenchymal tissue
- Solid variant comprised of haphazard arrangement of strands and cords of columnar and stellate epithelial cells and ghost cells
- Sheets of epithelial cells with clear appearing cytoplasm separated by thin fibrous connective tissue stroma may be identified:
 - Clear cells contain glycogen (diastase-sensitive, PAS-positive)
- Other findings may include presence of:
 - Cholesterol granuloma formation
 - Melanin pigment
- Approximately 20% associated with odontomas:
 - Usually unicystic
 - Combined features of CCOT and odontoma, latter characterized by:
 - Enamel matrix, dentin, and pulp
- Immunohistochemistry:
 - LEF-1, a nuclear transcription factor of Wnt pathway regulating multipotent skin stem cell differentiation:
 - Reported positive in 64% of CCOTs analyzed (7/11)
 - Strong diffuse staining also found in salivary gland basal cell adenoma (63%; 5/8) and basal cell adenocarcinoma (69%; 11/16)
 - β -Catenin, a transcriptional coactivator that interacts with LEF-1:
 - Nuclear staining reported in 83% of CCOTs analyzed (9/11)
 - Nuclear β -catenin also found in salivary gland basal cell adenoma (50%; 4/8) and basal cell adenocarcinoma (43%; 6/14)
 - Coexpression of LEF-1 and nuclear β -catenin found in all LEF-1-positive CCOTs
 - Findings indicate possible diagnostic utility of LEF-1 and β -Catenin in CCOT and in salivary gland tumors

Treatment and Prognosis

- Simple enucleation for unilocular lesions and enucleation with bony curettage for multilocular lesion considered adequate treatment
- Recurrent tumor:
 - May uncommonly occur with intraosseous lesions
 - Not reported in extraosseous lesions
- Follow-up including radiographic imaging recommended

- When associated with other tumor types (e.g., ameloblastoma) treatment and prognosis follow that of more aggressive tumor type
- May rarely undergo malignant transformation to ghost cell odontogenic carcinoma characterized by:
 - Solid proliferation of hyperchromatic and pleomorphic epithelial cells with abnormal mitoses and associated/admixed islands of ghost cells
 - Require wide local excision with tumor-free margins
 - May recur or metastasize resulting in patient death.

Odontogenic Myxoma

(Figs. 6-35 and 6-36)

Definition: Benign but locally invasive intraosseous neoplasm recapitulating mesenchymal portion of tooth-forming unit (i.e., dental papillae) characterized by presence of abundant myxoid or mucoid extracellular matrix with or without fibrous stroma and associated hypocellular component, including bland-appearing spindle-shaped to stellate to round-appearing cells.

Synonym: Odontogenic fibromyxoma

Clinical

- Considered an uncommon neoplasm
- No gender predilection; may occur over a wide age range from very young (first decade of life) to older individuals (eighth decade and older) but considered most common in second and third decades of life
- Most often occur in posterior tooth-bearing areas of mandible and maxilla:
 - More often identified in mandible than maxilla
- Small lesions are asymptomatic, but as lesions enlarge there is progressive swelling with bony expansion.
- Radiologic imaging findings vary and may include:
 - Small unilocular radiolucent lesion between roots of teeth
 - Large multilocular radiolucency
 - Borders vary from well defined with sclerotic margins to poorly defined with diffuse margins.
 - Often associated with root absorption and perforation of cortex
 - Variably described as soap bubble, honeycomb, tennis racket, or ground glass appearance
- Cause is unknown

Pathology

Gross

- On cut section surface appears homogeneous and translucent and gelatinous

Fig. 6-35. Myxoma of the mandible.

A, Pantomogram shows an ill-defined lesion with straight septa and tooth displacement (*arrowheads*). **B**, Axial CT (bone window setting) shows buccal expansion of the lesion with straight septa (*arrow*). (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 25-50, p 1502.)

Histology

- Unencapsulated, usually hypocellular proliferation composed of spindle-shaped to stellate to round-appearing cells embedded in myxoid stroma:
 - Areas of increased cellularity may be present.
 - Absence of significant nuclear pleomorphism and increased mitotic activity:
 - Binucleate cells and mitotic figures can be seen.

Fig. 6-36. Odontogenic myxoma.

A, Polypoid unencapsulated spindle-shaped proliferation embedded in myxoid stroma; odontogenic epithelium is focally present (*arrow*). **B** and **C**, Variably cellular proliferation composed of spindle-shaped to stellate to round-appearing cells lacking significant nuclear pleomorphism or increased mitotic activity as well as absence of complex curvilinear or plexiform vascular pattern that can be seen in sarcomas. In **B** odontogenic epithelium composed of columnar-appearing cells is seen, although such epithelium is only found in a small percentage of cases and is unnecessary in the diagnosis. **D**, The odontogenic epithelium is cytokeratin (AE1/AE3) positive.

- Variable amount of fibrous or collagenized stroma may be present in any case:
 - Based on the amount of fibrous stroma a designation of odontogenic fibromyxoma may be used.
- Nests or islands of odontogenic epithelium may or may not be present:
 - Rarely present (<10% of cases)
 - Not a requirement for diagnosis
- Nondescript vascularity lacking complex curvilinear or plexiform vascular pattern that can be seen in sarcomas
- Immunohistochemistry:
 - Spindle cells:
 - May be reactive for actins (smooth muscle and muscle specific)
 - Cytokeratins, S100 protein negative
 - If odontogenic epithelium is present will be reactive for cytokeratins (AE1/AE3, CK5, 7, 14, 19)
- Cytogenetics and molecular genetics:
 - Absence of guanine nucleotide-binding protein/ α -subunit (GNAS) mutation that is present in fibrous dysplasia

Differential Diagnosis

- Dental follicle (see Fig. 5-4):
 - Readily differentiated on basis of clinical and radiologic findings

- Dental follicle confined to crown of unerupted tooth and a few millimeters around it
- Dental follicle more collagenized than myxomas and may contain reduced enamel epithelium with numerous islands of odontogenic epithelium
- Dental papilla (see Fig. 5-5):
 - Represents formative dental pulp
 - May be separated from developing tooth during surgery and included in surgical specimen
 - Histologically distinguished from odontogenic myxoma by presence of odontoblasts close to surface and narrow cell-free zone beneath odontoblasts
- Odontogenic fibroma (Fig. 6-37):
 - Rare benign mesenchymal odontogenic neoplasm composed of fibrous, myxoid, and collagenized tissue with or without odontogenic epithelium
 - Divided into central and peripheral:
 - Central odontogenic fibroma (COF): originates in bone
 - Peripheral odontogenic fibroma: originates outside of bone (extragnathic) occurring in gingiva or attached alveolar ridge mucosa (in edentulous areas)
- Central odontogenic fibroma can be divided into two histologic variants, including:
 - Epithelial-poor type:
 - Noninfiltrating connective tissue lesion resembling dental follicle
 - Minimally cellular with dispersed collagen fibers
 - Fibromyxoid background
 - Scattered remnants of inactive-appearing odontogenic epithelium appear as small irregular islands and cords
 - Calcifications may be present.
 - Epithelial-rich-type:
 - Cellular fibroblastic connective tissue admixed with less cellular vascularized areas
 - Islands or strands of inactive-appearing odontogenic epithelium integral component and often conspicuous but may be sparse
 - Calcified material considered to be metaplastically produced dysplastic cementum or osteoid or dentin present
- Additional histologic variants described including:
 - Ameloblastomatoid
 - COF with numerous giant cells
 - COF with numerous granular cell
- Sinonasal myxoma/fibromyxoma; see Section 1, Sinonasal Tract

Fig. 6-37. Odontogenic fibroma.

Inactive-appearing odontogenic epithelium irregular-shaped island is present within a background of fibroconnective tissue.

Treatment and Prognosis

- Conservative surgery by enucleation and curettage can be performed for small lesions (smaller than 3 cm).
- Segmental resection with immediate reconstruction preferred for larger tumors
- Recurrence rates are high, ranging from 10% to 33% with an average of 25%:
 - Depends on extent of surgery
 - Long-term follow-up is required, in particular when conservative surgery is performed.
- Malignant transformation (odontogenic myxofibrosarcoma) exceedingly rare

BENIGN TERATOMA

Definition: Tumor composed of a variety of mature tissues derived from two or three germ layers and foreign to the site of occurrence.

- See Section 5, Neck, for complete discussion.

MALIGNANT TUMORS

POTENTIALLY MALIGNANT DISORDERS

Definition: Clinical presentations that may have a potential to become cancer conveying the concept of a multi-step process of cancer development, but unlikely, on a priori grounds, that there is uniformity in the way individual patients or tissues behave

- Use of term potentially malignant disorder conveys:
 - Not all lesions and conditions described under this term transform to cancer.
 - There is a group of morphologic alterations, among which some may have an increased potential for malignant transformation.
 - Potentially malignant disorders of oral mucosa are also indicators of risk of likely future malignancies elsewhere in (clinically normal-appearing) oral mucosa and not only site-specific predictors.

Synonyms: Pre-cancer, precursor lesions, epithelial precursor lesions; premalignant lesions; intraepithelial neoplasia

- Oral potentially malignant disorders include (but may not be limited to):
 - Oral leukoplakia (including proliferative verrucous leukoplakia)
 - Oral erythroplakia
 - Actinic keratosis (cheilitis)
 - Oral submucous fibrosis (see previous chapter)
 - Palatal lesions in reverse smokers:
 - Specific to populations who smoke with the lighted end of the cigar, cigarette, or cheroot inside the mouth, resulting in red, white, or mixed lesions of the palate
 - All changes related to this habit are noted on palate.
 - Lichen planus:
 - Considerable controversy as to its potentially malignant nature
 - See previous chapter
 - Oral discoid lupus erythematosus (DLE):
 - Conflicting data in literature regarding whether oral DLE is a potentially malignant disorder
 - Hereditary disorders that may have an increased risk of malignancy in the mouth include:
 - Dyskeratosis congenital
 - Epidermolysis bullosa
- This section focuses on only oral leukoplakia, proliferative verrucous leukoplakia, oral erythroplakia, and actinic cheilitis.

Oral Leukoplakia (OL)

(Figs. 6-38 through 6-40)

Definition: Clinical term for a white mucosal lesion (plaque or patch) that cannot be rubbed or scraped off and that is not recognized (clinically or pathologically) as any other disease.

◦ *Leuko* means white and *plakia* means patch.

Synonyms: Keratosis; hyperkeratosis

Clinical Features

- Estimated prevalence of oral leukoplakia, worldwide, is approximately 2%:
 - Incidence increases with age
- More common in men than in women; most common in the fifth through seventh decades of life:
 - Uncommon in younger age groups (less than 30 years of age).
- Occurs most commonly on the vermilion border of the lower lip, buccal mucosa, and gingiva; less common locations include the tongue (lateral and ventral), palate (hard and soft), and floor of mouth
- Clinical diagnosis of leukoplakia is not necessarily an indicator and does not necessarily correlate with histopathologic confirmation of an underlying dysplasia:
 - Precancerous potential of leukoplakia is well established, is more often predicated on the facts that keratosis is associated with an increased risk of malignant transformation as compared with nonkeratotic oral lesions and that keratosis is present in a significant percentage (greater than one third of cases) of oral carcinomas.
 - Of all oral leukoplakias from 9% to 37% represent dysplasia, carcinoma in situ, or invasive carcinoma at time of biopsy.
 - Overall risk of dysplasia transforming to invasive carcinoma is estimated to be approximately 16% to 36%.
 - There is a correlation between the site of leukoplakia and the incidence of an associated dysplasia:
 - Greatest frequency of epithelial dysplasia is found in leukoplakic lesions of the floor of mouth, tongue (lateral and ventral), and vermilion border of the lip
- Cause:
 - Includes tobacco use, trauma, microorganisms, ultraviolet radiation:
 - Arguably, most common cause of oral leukoplakia is due to tobacco, a finding supported by the fact that:

Fig. 6-38. Clinical appearance of oral leukoplakia.

Oral leukoplakia including (A) homogeneous leukoplakia appearing as thin, white confluent flat area involving the right ventral tongue and floor of mouth; (B) relatively small, thin, flat, and well-demarcated patch of homogeneous leukoplakia of the ventral tongue; (C) nonhomogeneous leukoplakia appearing as a thick, white lesion with increased surface irregularities of the ventral tongue; (D) nonhomogeneous leukoplakia appearing as a thick, white plaque with fissures.

(From Woo S: *Oral pathology*, Philadelphia, 2012, Elsevier, Fig. 11-1.)

- Smokers are more prone to have leukoplakia than nonsmokers.
- Heavy smokers have larger and more numerous leukoplakic lesions than nonsmokers.
- Cessation of tobacco use often results within 1 year in the disappearance or reduction in the size of leukoplakic lesions.
- Also may be caused by chronic irritation due to friction (frictional keratosis) and chemicals (chemical keratosis):
 - Frictional keratosis is a common finding in areas where chronic (persistent or recurring) mild irritation occurs.
 - Causes include ill-fitting dental prosthetics, chronic cheek biting or lip biting, exuberant toothbrushing, as well as the use of smokeless tobacco.
 - Chronic exposure to chemical compounds may result in leukoplakia, including those found in smokeless tobacco, medications (e.g., aspirin), and spices (e.g., peppermint, cinnamon).
- Nicotinic stomatitis is another form of chemically or thermally induced leukoplakia, representing a generalized whiteness of the palate in people who smoke cigars and pipes:
 - Fact that these changes are more likely a result of heat rather than chemicals is a reason that this type of leukoplakia has limited to no malignant potential
- Leukoplakic lesion associated with irritation is reversible after elimination of the irritant; further, this type of lesion is not considered to have malignant potential.
- Microorganisms that may be associated with oral leukoplakia include *Candida albicans* and *Treponema pallidum*, the causative agent for syphilis:
 - *Candida* infestation of the squamous epithelial layers may result in a leukoplakic or

Fig. 6-39. Histology of (oral) leukoplakia.

The histologic features corresponding to a clinical leukoplakic lesion may include a wide spectrum of changes falling within the general category of keratosis with or without dysplasia. The following examples all represent varying degrees of (hyper)keratosis without dysplasia and progressive changes in the architectural features. **A**, Flat epithelium with orthokeratosis and absence of dysplasia. **B**, Orthokeratotic squamous epithelium with hypergranulosis and slightly elongated and downwardly extending rete ridges without dysplasia. **C**, Parakeratotic squamous epithelium with greater degree of elongated and downwardly extending rete ridges without dysplasia. The presence of inflammation in the submucosa does not affect the diagnosis, treatment, or prognosis.

- erythroplakic lesion (candidal leukoplakia); antifungal therapy usually results in diminishing or disappearance of the lesion.
- *Candida albicans* can be present in the oral cavity of up to 50% of the normal population.
- Tobacco smoking is considered to represent a predisposing factor in oral *Candida* infection.
- Whether candidal infestation represents secondary colonization or is the cause of leukoplakia is debatable, but the clinical leukoplakic lesion and the histopathologic keratosis with concurrent epithelial changes associated with

Candida infection may simulate the appearance of a squamous cell carcinoma.

- Conflicting findings related to possible role of human papillomavirus infection
- Ultraviolet radiation may cause leukoplakia of the lower lip referred to as actinic cheilosis (see later).

Pathology

Gross

- Leukoplakic lesions vary in appearance from:
 - Thin, white to gray plaque that may appear wrinkled, flat, or translucent (so-called thin or early leukoplakia)

Fig. 6-40. Verruoid (hyper)keratosis without dysplasia.

A and B, Low magnification shows prominent verruoid (hyper)keratosis with associated irregular epithelial hyperplasias including elongated and downwardly extending rete ridges. **C and D,** At higher magnifications, the epithelial cells lack dysplastic changes. These overall features could be those of proliferative verrucous leukoplakia (PVL) or even verrucous carcinoma, but in contrast to these other lesions after excision there were no recurrences and/or progression of the lesion. Nevertheless, purely on the basis of the histologic findings differentiation between verruoid hyperplasia, PVL, and verrucous carcinoma is not possible. In this setting, complete excision is recommended with close clinical follow-up. If such a lesion recurs, persists, or progresses, then it is likely to represent PVL or verrucous carcinoma.

- Thicker lesion with a distinct white appearance, leathery consistency, and deeper mucosal fissures (so-called thick or homogeneous leukoplakia)
- Thick, white lesion with increased surface irregularities (so-called granular, nodular, or nonhomogeneous leukoplakia)

Histology

NOTE: Leukoplakia (as well as erythroplakia and speckled leukoplakia) are clinical and not histopathologic terms; these clinical designations should not be used in the microscopic diagnosis.

- Histology of leukoplakic lesions includes hyperkeratosis representing thickened keratin layer on the

surface epithelium with a thickened spinous layer (acanthosis) that may in turn be associated with:

- Parakeratosis (loss of the granular layer with the presence of nuclei in the thickened keratin layer)
- Orthokeratosis (retention of the granular layer with an absence of nuclei in the thickened keratin layer)
- Variable mixed chronic inflammatory cell infiltrate is present in the submucosa.
- Majority of leukoplakic lesions are devoid of epithelial dysplasia or have dysplastic changes limited to the basal zone; however, the full spectrum of epithelial dysplasia ranging from mild, moderate, and severe dysplasia may be present:

- Diagnosis of dysplasia is primarily predicated on cytomorphologic changes but also incorporate architectural changes (see Section 5, Larynx).
- Histochemistry:
 - In presence of a neutrophilic infiltrate of the surface epithelium a fungal infection should be considered.
 - To this end, special stains for microorganisms (e.g., Gomori methenamine silver, periodic acid Schiff) should be performed.
 - Presence of fungal forms (hyphae, spores) within the depth of the surface epithelium would be indicative of fungal infestation; the latter as previously noted may be associated and perhaps is the cause of clinical leukoplakic lesions.
 - Histologically, there may only be hyperkeratosis and irregular epithelial hyperplasia without dysplasia, but, in conjunction with the microorganisms, there may be a concomitant significant dysplasia and/or carcinoma.
 - In fungal colonization microorganisms are limited to the keratin layer or the very superficial epithelium.
- Immunohistochemistry:
 - Literature is replete with studies evaluating the utility of various antibodies in the diagnosis of dysplastic epithelial lesions and in potential use in predicting malignant transformation, but there are no individual markers that consistently or reliably predict malignant transformation.
- Cytogenetics and molecular genetics:
 - In spite of tremendous progress in field of molecular biology, there is as yet no single marker or set of markers that reliably allows for predicting the malignant transformation of OL in an individual patient.
 - DNA ploidy and loss of heterozygosity (LOH) have been extensively evaluated:
 - DNA ploidy:
 - High predictive value of aneuploidy in dysplastic leukoplakic and erythroplakic lesions (and to some extent nondysplastic leukoplakic lesions) in identification of progression to carcinoma
 - No correlation between the degree of dysplasia and DNA ploidy
 - LOH:
 - LOH on chromosomes 9p21 and 3p14 have greater probability of progression to squamous cell carcinoma.

Differential Diagnosis

- Reactive hyperplasia
- Pseudoepitheliomatous hyperplasia
- Infectious (i.e., fungal) disease
- Squamous cell carcinoma

Treatment and Prognosis

- Treatment of a leukoplakic lesion is predicated on the histopathologic findings associated with this lesion; as such, biopsy of a leukoplakia is required:
 - Owing to the fact that leukoplakic lesions often have a markedly thickened keratin layer, clinicians should bear in mind that a biopsy of the lesion should be deep enough to include the epithelial-to-stromal interface.
 - Any biopsy falling short of including this interface may be insufficient for histopathologic review and diagnosis.
 - Multiple biopsies may be required, especially if the leukoplakia is large or extensive.
- In the presence of an adequate sample (i.e., to include the epithelial-to-stromal interface) a histologic diagnosis of:
 - Hyperkeratosis without dysplasia or with mild dysplasia does not require additional treatment but should necessitate vigilant follow-up (e.g., at 6-month intervals).
 - Hyperkeratosis with moderate or severe dysplasia (i.e., high-grade intraepithelial dysplasia) necessitates additional treatment, including complete removal of the lesion by surgical excision, electrocautery, cryosurgery, laser ablation:
 - Vigilant follow-up in these patients is also needed.
 - In addition, if a patient is known to use tobacco products, all efforts to eliminate the use of tobacco are recommended.
- Annual malignant transformation ranges from 2% to 3%.
- At present, no reliable clinicopathologic or molecular predicting factors of malignant transformation
- Risk factors that may be associated with increased potential to malignant transformation of oral leukoplakia but are not absolute indicators include:
 - Long duration of leukoplakia
 - Homogeneous thick leukoplakia:
 - May undergo malignant transformation from 1% to 7% of cases
 - In presence of surface granularity or verruciform appearance the risk of potential to malignant transformation rises from 4% to 15%
 - Thin leukoplakia seldom becomes malignant.
 - Female gender
 - Occurrence in the absence of smoking history (smokeless or cigarette/cigar use)
 - Localization on the tongue or floor of mouth
 - Size ≥ 4 cm showed to be predicting factor of malignant transformation in oral leukoplakia
 - Presence of epithelial dysplasia:
 - Often dependent on the extent of dysplasia with the incidence of hyperkeratosis with mild

dysplasia progressing to more severe dysplasia or carcinoma being low and the incidence of hyperkeratosis with moderate or severe dysplasia progressing to carcinoma significantly higher than that of mild dysplasia.

Proliferative Verrucous Leukoplakia (PVL) (Fig. 6-41)

Definition: Aggressive irreversible form of oral leukoplakia with a tendency to recur, often with multifocal oral involvement, and to undergo malignant transformation to either verrucous carcinoma or conventional squamous cell carcinoma.

- Diagnosis is determined clinicopathologically and usually made in retrospect.
- A recent proposal for a diagnosis of PVL required:

- Involvement of more than two oral cavity subsites
- Total added size of leukoplakic areas of at least 3 cm
- Well-documented period of at least 5 years of disease evolution being characterized by spreading and occurrence of one or more recurrences in a previously treated area

Synonym: Verrucous hyperplasia

Clinical Features

- Uncommon lesion
- More common in women than men (4:1); most common in elderly women over 60 years of age with mean age in eighth decade of life
- Typically occurs in the setting of a long history (decades) of oral leukoplakia

Fig. 6-41. Proliferative verrucous leukoplakia.

A, Older white female with persistent and progressive leukoplakic lesion of the oral cavity for many years presented with large confluent white patch of her buccal mucosa. **B**, Verrucoid squamous epithelial proliferation markedly elongated rete ridges, but the epithelial proliferation remains superficial (without submucosal invasion) and does not extend deeper than the adjacent normal epithelium seen along the extreme left side of the image. **C** and **D**, At higher magnification, the epithelial cells lack dysplastic changes; scattered mitotic figures are present (arrows) in the basal zone epithelium. The histologic diagnosis of PVL is problematic and typically requires clinicopathologic correlation and usually is made retrospectively after persistent, recurrent, and progressive leukoplakic intraoral lesions.

- Most common on buccal mucosa or oral tongue but also may involve gingiva, alveolar mucosa, floor of mouth, palate, and lip
- Risk factors:
 - No known risk factors associated with PVL including use of smokeless tobacco, smoked tobacco, alcohol, areca nut use
 - A history of tobacco use is present in a high percentage of patients (greater than 50%), but a significant minority of patients have no history of tobacco use.
 - Human papillomavirus (HPV) PVL has been reported, but etiologic significance of HPV in development of PVL remains unproven.

Pathology

NOTE: Diagnosis of PVL in its early stages is virtually impossible due to the innocuous appearance of the lesions and overlapping clinical and pathologic features with other types of leukoplakic lesions.

Gross

- Clinically, the lesion is a flat, thickened keratosis with the histologic appearance of a nondysplastic keratosis.
- With progression of disease, the lesions become multiple, multifocal, and confluent, with an exophytic and/or warty (verruroid) appearance; it is in the latter clinical form that squamous cancer (verrucous carcinoma or conventional squamous cell carcinoma) is seen.

Histology

- Composed of hyperplastic squamous epithelium with regularly spaced, verrucous epithelial projections, and associated hyperkeratosis
- Sharply defined lesion with hyperplastic epithelium remaining superficial (without submucosal invasion) and does not extend deeper than that of the adjacent epithelium:
 - Above feature contrasts with the downward growth into the underlying submucosal com-

partment by the bulbous rete ridges in verrucous carcinoma

- Lichenoid inflammatory infiltrate is uncommon.
- Any given lesion may show a combination of verrucous hyperplasia, verrucous carcinoma, and conventional well-differentiated squamous cell carcinoma.
- To exclude the presence of submucosal invasion, complete excision of the lesion allowing for histologic examination of the entire lesion is most appropriate:
 - Adequate sampling is imperative; otherwise, there will be diagnostic and differential diagnostic problems on incisional biopsy material.
- Cytogenetics and molecular genetics:
 - Loss of heterozygosity at chromosome 9p loci:
 - Represent a similar finding found for dysplastic premalignant lesions of oral cavity
 - p53 gene mutations not identified, although variable p53 expression reported
 - Homozygous deletion of exon 1β of p14 gene reported:
 - Similar findings identified in squamous cell carcinoma, affirming aggressive nature of PVL
 - Larger prospective, multicenter studies including sequentially acquired lesions with comparative analysis are needed to better determine molecular, genetic, and epigenetic alterations associated with PVL.

Differential Diagnosis (Table 6-2)

- Reactive (nonspecific) verrucoid hyperplasia and verrucous hyperkeratosis
- Oral leukoplakia
- Verrucous carcinoma

Treatment and Prognosis

- Surgical management is preferred treatment:
 - Generally unsuccessful owing to inherent geographic spread and progressive nature of PVL
 - Disease-free survival rates after surgery are low due to recurrence and multifocal involvement.

TABLE 6-2 Proliferative Verrucoid Leukoplakia (PVL): Differential Diagnosis

	PVL	COL	VC
Gender	F > M (4:1)	M > F (2:1)	M ≫ F
Age	>60; mean 8th decade	Younger ages	Elderly
Most common sites	Oral cavity, tongue	Anywhere in oral cavity	Buccal mucosa, larynx
Risk factor(s)	Unknown	Tobacco, others	Tobacco
Presence of dysplasia	Rare	Low (5% to 15%)	No
Progression to malignancy	High*	Low (1% to 2%)	Yes

COL, Conventional oral leukoplakia; VC, verrucous carcinoma.

*To verrucous carcinoma and/or conventional squamous cell carcinoma.

- Nonsurgical treatments include:
 - Radiotherapy, topical agents, cryotherapy, and phototherapy not shown to be effective in controlling disease.
- Therapeutic goal may be one of control rather than cure, maintaining surveillance to detect invasive cancer early requiring wide excision
 - Radiotherapy should be reserved for invasive carcinoma with aggressive features.
- Early recurrence is common, usually accompanied by greater extension and an increase of epithelial changes including dysplasia
- Malignant transformation to verrucous carcinoma and/or conventional squamous cell carcinoma is almost always the outcome.
 - Given that PVL is associated with VC in a high percentage of cases, some authors believe that PVL should be considered as a premalignant condition or an early biologic form of VC and treated accordingly.
- Such a consideration would obviate the confusion, both clinically and pathologically, that surrounds the use of the term verrucous hyperplasia in describing these oral cavity lesions.
- Prognosis considered poor:
 - In one study of 30 patients followed from 1 to 20 years:
 - 13 of 30 (43%) of patients died of or with their disease (persistent or recurrent)
 - 14 of 30 (20%) were alive with disease
 - 3 of 30 (10%) were alive without PVL

Oral Erythroplakia (Fig. 6-42)

Definition: Clinical term for a red mucosal lesion (plaque or patch) that cannot be rubbed or scraped off and that is not recognized (clinically or pathologically) as any other disease:

- Erythroplakia represents the red equivalent of leukoplakia.

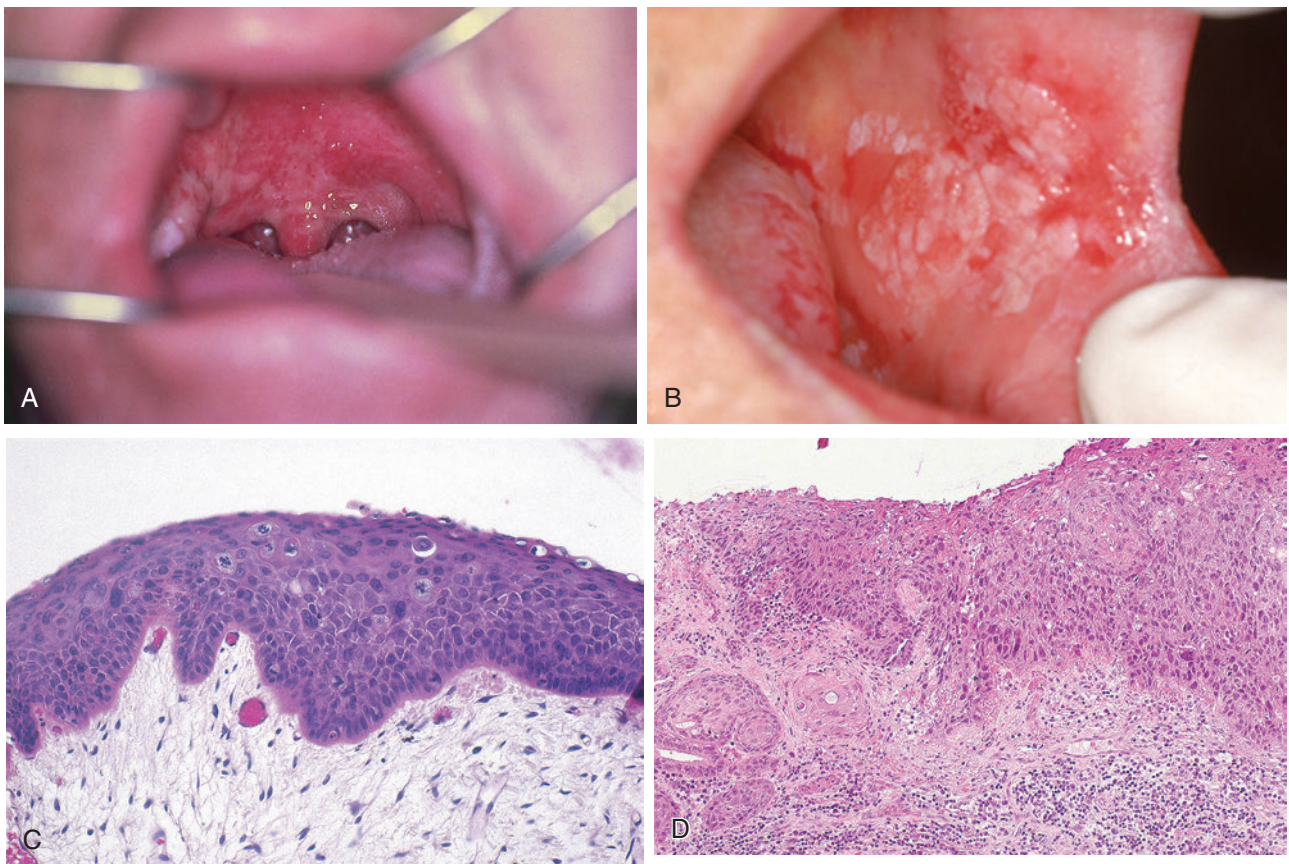

Fig. 6-42. Oral erythroplakic lesions.

A, Diffuse erythroplasia of the palate and uvula. **B**, Irregular-appearing erythroleukoplakic lesion of the left buccal mucosa. The corresponding histologic findings often include a significant dysplastic lesion including **(C)** high-grade intraepithelial dysplasia and **(D)** invasive squamous cell carcinoma (arrows).

- Red areas associated with leukoplakic lesions are referred to as erythroleukoplakia, speckled leukoplakia, or speckled mucosa:
 - More common than purely red (erythroplakic) lesion

Clinical

- Less common lesion than leukoplakia with prevalence between 0.02% and 0.83%
- No distinct gender predilection; most common in patients older than the fifth decade of life:
 - Uncommon in younger age groups (less than 30 years of age)
- May be asymptomatic, appearing as a solitary red mucosal, sharply demarcated, flat lesion with smooth or granular surface:
 - Similar to clinical presentation for early (asymptomatic) oral squamous cell carcinoma
 - Solitary lesion helpful in clinically distinguishing erythroplakia from erosive lichen planus, lupus erythematosus, and erythematous candidiasis, because these lesions occur almost always in a bilateral, more or less symmetric pattern.
- Occurs most commonly on floor of the mouth, tongue (lateral and ventral), soft palate, tonsillar region, and retromolar region:
 - Dorsal tongue rarely involved
- In contrast to leukoplakia, presence of erythroplakia may correlate to an underlying significant dysplasia (i.e., moderate to severe dysplasia) or to carcinoma:
 - Not all red erythroplakic lesions herald dysplasia/carcinoma, because many red oral mucosal lesions may be inflammatory.
- Cause:
 - Tobacco and alcohol important factors

Pathology

Gross

- Well-circumscribed erythematous, velvety, or granular plaque

Histology

- Squamous epithelial proliferation characterized by:
 - Absence of surface keratinization
 - Commonly shows moderate to severe (i.e., high-grade) dysplasia ranges:
 - Majority of clinical erythroplakic lesions have histologic changes of severe dysplasia
 - Severe dysplasia/carcinoma in situ present in 40% of cases
 - Invasive carcinoma present in >50% of cases
 - Absence of keratinization coupled with presence of epithelial dysplasia would allow classification as nonkeratinizing (“classical”) dysplasia.

- Epithelial alterations varying from atrophic to hyperplastic with submucosal nonspecific inflammation and dilated capillaries
- Cytogenetics and molecular genetics:
 - No individual markers that consistently or reliably predict malignant transformation
 - DNA ploidy and loss of heterozygosity (LOH) have been extensively evaluated:
 - DNA ploidy:
 - High predictive value of aneuploidy in dysplastic leukoplakic and erythroplakic lesions (and to some extent nondysplastic leukoplakic lesions) in identification of progression to carcinoma
 - No correlation between the degree of dysplasia and DNA ploidy
 - LOH:
 - LOH on chromosomes 9p21 and 3p14 have greater probability of progression to squamous cell carcinoma.

Differential Diagnosis

- Inflammatory lesions
- Atrophic oral lichen planus

Treatment and Prognosis

- In general, erythroplakia must be treated because of its high risk of malignant transformation.
- Surgery, either by cold knife or by laser excision, is recommended treatment.
- No data from the literature about the recurrence rate after excision of erythroplakias, but recurrence and multifocal oral mucosal involvement occur frequently and vigilant follow-up in these patients is required
- Progression to malignant transformation ranges from 18% to 47% with an average of approximately 28%.

Actinic Cheilitis (Fig. 6-43)

Definition: Premalignant lesion of the vermilion border of the lip, especially the lower lip due to long-term exposure to the ultraviolet radiation of sunlight.

Synonyms: Solar cheilosis; solar cheilitis; farmer’s lip; sailor’s lip

Clinical Features

- More common in men than in women and does not typically occur in patients younger than the fifth decade of life
- Occurs almost exclusively in Caucasians, especially those with fair skin
- Closely correlated with total cumulative exposure to sunlight with increased prevalence in those who

Fig. 6-43. Actinic cheilitis.

A, Leukoplakic lesion of the lower lip with loss of the distinct demarcation between the lower lip vermilion border and the skin of the lip. **B**, Corresponding histologic findings include hyperkeratosis with orthokeratosis, atrophy of the surface (squamous) epithelium with loss of rete ridges, intraepithelial high-grade dysplasia, and solar (actinic) elastosis of the submucosa.

work out of doors, such as farmers, sailors, beach workers

- Because the lesions develop slowly, patients are usually not aware of changes.
- Lower lip vermilion is the most common site of occurrence.
- Early changes include local puffiness and atrophy, characterized by a smooth and blotchy-appearing, pale to erythematous area:
 - Normally distinct demarcation between the lower lip vermilion border and the skin of the lip becomes indistinct or blurred.
- With progression the lesion becomes rough and scaly and may thicken, becoming leukoplakic; lesions may ulcerate especially secondary to trauma:

- Ulceration is usually painless and may last for several months.
- Overall appearance simulates a squamous cell carcinoma; however, in contrast to carcinoma, the lesions of actinic cheilitis do not become indurated.
- Overall process is similar to that of the cutaneous actinic keratosis.

Pathology

Histology

- Similar to cutaneous actinic keratosis, including:
 - Hyperkeratosis with parakeratosis and/or orthokeratosis
 - Surface (squamous) epithelial atrophy, including loss of rete ridges
 - Epithelial dysplasia ranging from mild to severe invariably present
 - Subjacent stroma with solar damage (solar or actinic elastosis) characterized by the presence of acellular, basophilic change due to breakdown of collagen secondary to ultraviolet light damage

Differential Diagnosis

- Erosive lichen planus
- Lupus erythematosus of the lip mucosa

Treatment and Prognosis

- Irreversible process; nevertheless in the majority of cases surgical intervention is not immediately indicated.
- Treatment includes limiting exposure of the area to the damaging effect of sunlight by the use of lip balm and/or sunscreen.
- Those cases in which the clinical findings are worrisome for carcinoma may require biopsy to exclude a diagnosis of squamous cell carcinoma.
- In those circumstances in which progressive (more severe) epithelial dysplasia may be present, lip mucosal stripping (i.e., vermillionectomy) may be required:
 - Vermilionectomy remains the standard for efficacy.
- Up to 10% of cases undergo malignant transformation to well-differentiated squamous cell carcinoma:
 - Malignant transformation often takes years, typically does not occur in patients under 60 years of age, and develops so slowly that there are minimal morbidity (e.g., metastases) and negligible mortality due to disease.
 - In the presence of squamous cell carcinoma more extensive surgical intervention is required.
 - Metastatic squamous cell carcinoma arising from actinic cheilitis may occur.

Keratinizing and Nonkeratinizing Dysplasia

Definition: Alteration in a malignant direction in the appearance of epithelial cells with an increased likelihood to progress to squamous cell carcinoma.

Synonyms: Keratosis with atypia; atypia; mild dysplasia; moderate dysplasia; severe dysplasia; squamous intraepithelial lesion (SIL); squamous intraepithelial neoplasia (SIN); laryngeal intraepithelial lesion (LIN); laryngeal intraepithelial lesion (LIL); simple hyperplasia; basal/parabasal hyperplasia; atypical hyperplasia

- Causes include:
 - Tobacco use:
 - Most common associated risk factor
 - Up to 90% of patients with oral leukoplakia use tobacco products (smokeless tobacco; cigarettes, pipe)
 - Excess alcohol use:
 - Alcohol potentiates the effect of tobacco smoking.
 - Risk of developing dysplastic lesions increases with duration of smoking with or without alcohol use
 - Chronic infections, including fungal infection:
 - *Candida albicans* is ubiquitous in the oral cavity in normal populations.
 - Tobacco smoking can be a predisposing factor for oral candidal infection.
 - Whether fungi cause dysplasia or are secondary colonizers in the presence of dysplasia remains uncertain.
 - Role of human papillomavirus (HPV) in the oral cavity intraepithelial dysplastic lesions remains unproven.
 - High-risk HPV uncommon finding in head and neck squamous cell carcinoma from patients who have history of tobacco or alcohol use
- See Section 5, Larynx and Trachea, for a more complete discussion and illustrations.

HEAD AND NECK CARCINOMA

General Considerations

- Majority of head and neck cancers arise from the surface mucosa and are squamous cell carcinomas
- Worldwide incidence of head and neck cancer exceeds half a million cases, annually ranking it the fifth most common cancer worldwide.
- In the United States, 52,000 people develop head and neck cancer annually and 11,500 die from disease.
- Head and neck squamous cell carcinoma (HNSCC):
 - Second only to lung cancer as most common smoking-related cancer
 - Treatment often results in substantial morbidity.

- Mutational cause is diverse with few targetable mutations.
- Risk factors associated with HNSCC:
 - Primary risk factors include tobacco use and alcohol consumption
 - Tobacco and alcohol have synergistic effect on the risk of developing HNSCC.
 - Betel nut chewing, widespread in regions of Asia, is an independent risk factor for development of HNSCC.
 - Oncogenic viruses:
 - HPV associated with oropharyngeal carcinomas (see Section 3, Pharynx)
 - EBV associated with nasopharyngeal carcinomas (see Section 3, Pharynx)
 - HIV-infected patients have increased relative risk of 2- to 3-fold to develop HNSCC.
 - Conventional keratinizing squamous cell carcinoma of oral cavity and variants thereof not known to be associated with any oncogenic viruses
 - Genetic alterations may contribute to increase in risk of HNSCC.
- Genetics of HNSCC:
 - Hallmarks of cancer necessary for a malignant tumor to develop include:
 - Acquisition of sustained proliferative signaling
 - Evasion of growth suppressor signals
 - Resistance to cell death (evasion of apoptosis)
 - Replicative immortality (immortalization)
 - Induction of angiogenesis
 - Activation of tissue invasion and metastasis
 - Dereglulation of cellular energy metabolism
 - Evasion of immune destruction
 - Additional enabling characteristics include:
 - Genome instability and mutation
 - Tumor-promoting inflammation
 - Molecular mechanisms underlying malignant change in upper aerodigestive tract include genetic and epigenetic causes:
 - Common genetic alterations in HNSCC include:
 - Deletions, translocation, isochromosomes, and less frequently amplifications
 - Losses of genomic material more frequent than gains and affect:
 - 3p, 9p, 21q, 5q, 13q, 18q, and 8p
 - ◻ Loss of heterozygosity at 3p14 early genetic alteration
 - ◻ Loss of heterozygosity at 9p21 occurs early in progression of HNSCC
 - ◻ Loss of heterozygosity chromosome region 17p13 is a late genetic alteration
 - Tumor suppressor genes or oncogenes associated with chromosomal alterations include:
 - Loss of 3p associated involves *FHIT* and *RASSF1A*

- Loss of 9p21 associated with *CDKN2A*
- Loss of 17p13 associated with *TP53*
- Gains of genomic material associated with HNSCC include:
 - Gain in 3q, among the most frequent gain and includes *TP63* (an epithelial development gene) and *PIK3CA*
 - Gain in 7p includes *EGFR*
 - Gain in 8q includes *MYC* oncogene
 - Gain in 11q13 includes *CCDN1*
- Genetic progression model for HNSCC has been proposed, including:
 - Loss of 9p leading to inactivation of *CDKN2A*, an early event found in 70% of HNSCC, frequently followed by loss of 3p (*FHIT*, *RASSF1*) and 17p (*TP53*) in transition to dysplasia
- Recent molecular evaluation of mutational landscape of HNSCC using whole exome-sequencing technology and gene copy number analyses showed:
 - Tumors from patients with a history of tobacco use had more mutations than tumors from patients who did not use tobacco.
 - Tumors that were negative for human papillomavirus (HPV) had more mutations than did HPV-positive tumors.
 - Most frequent somatic mutations found in *TP53*, *CDKN2A*, *PIK3CA*, *HRAS*, *FBXW7*, and *NOTCH1*
 - Nearly 40% of 28 mutations identified in *NOTCH1* were predicted to truncate the gene product, suggesting that *NOTCH1* may function as a tumor suppressor gene rather than an oncogene in HNSCC.
 - Two new genes, *CEBPA* and *FES*, were recently identified, extending the spectrum of HNSCC mutations.
 - Significant proportion of mutated genes are involved epidermal development and squamous differentiation
- Cancer epigenetics: study of epigenetic modifications to genome of cancer cells not involving a change in the nucleotide sequence:
 - Mechanisms of epigenetic silencing of tumor suppressor genes and activation of oncogenes include:
 - DNA methylation
 - Histone modifications
 - Dysregulation of DNA binding proteins
 - Epigenetic changes in HNSCC include inactivation of individual tumor suppressor genes, including:
 - *CDKN2A*, *CDH1*, *DAPK1*, *RASSF1*, *RAR-β*, *DCC*, *MGMT*, *NDRG2*, *DLEC1*
 - More recently, integrated molecular analysis based on methylation binding domain sequencing, 450K methylation arrays, whole exome sequencing, and whole genome gene expression arrays in primary head and neck squamous cell carcinoma (HNSCC) tumors:
 - Uncovered 186 downregulated genes harboring cancer-specific promoter methylation, including *PAX1* and *PAX5*
 - Identified 10 key tumor suppressor genes including *GABRB3*, *HOXC12*, *PARP15*, *SLCO4C1*, *CDKN2A*, *PAX1*, *PIK3AP1*, *HOXC6*, *PLCB1*, and *ZIC4*) inactivated by promoter methylation and/or somatic mutation.
 - Among the novel tumor suppressor genes discovered with dual mechanisms of inactivation, a high frequency of genomic and epigenomic alterations in the paired box (PAX) gene family of transcription factors, which selectively affect canonical NOTCH and TP53 pathways to determine cell fate, cell survival, and genome maintenance
 - Such findings highlight the importance of assessing tumor suppressor genes at genomic and epigenomic levels to identify key pathways in HNSCC, deregulated by simultaneous promoter methylation and somatic mutations.
- “Field cancerization” (Fig. 6-44):
 - Multiple, independent carcinogenic events occur in separate cells due to exposure of the “preconditioned epithelium” or “condemned mucosa” to a carcinogenic agent
 - Field of preconditioned epithelium or “condemned mucosa” (i.e., mucosa rendered more susceptible to tumor formation) becomes activated or breaks down into cancer, producing multiple separate carcinomas rather than from a single cell that becomes malignant.
 - Subsequent studies confirmed the “field cancerization” phenomenon, in which significant dysplastic changes affect a wide epithelial mucosal field in patients at high risk for developing cancer (e.g., heavy smokers and drinkers) with identification of similar genetic alterations in matched dysplastic and malignant lesions in oral cavity.
 - Concept of “field cancerization” and “condemned mucosa” explain the greater risk to the head and neck cancer patient for development of a second primary malignancy, which in turn plays a significant role in the tendency for these tumors to recur or persist despite therapeutic intervention, with adverse impact on survival.
 - Frequent development of synchronous or metachronous second or multiple primary cancers in

Fig. 6-44. Field cancerization.

A, Depiction of the initial hypothesis that multiple carcinogenetic events occur in separate cells leading to the development of independent cancerous foci. **B,** Alternative hypothesis confirmed in several studies shows that a single focus of carcinoma develops and spreads laterally without disruption of the adjacent apparently normal mucosa.

the head and neck and/or lung support concept of field cancerization:

- Second tumor may be clonally similar to or distinct from the primary tumor.
- Alternative hypothesis suggested that a single focus of tumor develops and spreads laterally by

arborization without disrupting adjacent normal mucosa:

- Synchronous but separate carcinomas (primary floor of mouth and piriform sinus lying 6 to 7 cm apart) and metachronous carcinomas (recurrences of these tumors after

radiotherapy) in a single patient evaluated to determine whether the tumors were of common or independent clonal origin

- Histologically, the two tumors shared a similar morphology, including invasive moderate to poorly differentiated keratinizing squamous cell carcinomas.
- All four tumors found to be of monoclonal origin, suggesting that in some patients second primary cancers may arise at distant sites because of the lateral spread of malignant clones
- Lateral spread presupposes the multiple factors required for active neoplastic cell motility with penetration of extracellular matrices.
- Other studies using X chromosome inactivation and LOH analysis in multiple HNSCC from female patients show high probability that second primary tumors were progeny of the same clone, supporting the idea that many second primary tumors represent extensions of the initial tumor clone.
- Use of molecular markers has validated concept of field cancerization:
 - Oral epithelium evaluated for use as surrogate tissue for assessing tobacco-induced molecular alterations in lungs by studying methylation status of CDKN2A and FHIT in oral and bronchial brush specimens from smokers enrolled in chemoprevention trial showed:
 - Dose-response relationship between number of sites methylated in lung and presence of oral methylation observed for CDKN2A
 - Other studies have shown concomitant methylation of three or more genes in sputum associated with greater than sixfold increase in risk for lung cancer.
 - Global gene expression changes have been reported in response to cigarette smoke throughout respiratory tract, including bronchus, nose, and mouth.
- Mutagen sensitivity:
 - Although exposure to a carcinogen is critical to the potential development of a head and neck malignancy, host-specific factors also influence cancer risk by modulating the susceptibility to carcinogenetic agents.
 - Individual response to the mutagenic activity of exogenous agents resulting in defective DNA repair mechanisms, referred to as mutagen sensitivity, is a complex phenomenon involving multiple genetic factors.
 - Mutagen sensitivity has been reported to be a significant risk factor for HNSCC, and the interaction between cigarette smoking and mutagen sensitivity has been shown to have a multiplicative effect.
 - Clinical follow-up of the mutagen-sensitive head and neck cancer patient has shown these patients to be at greater risk to develop a second primary malignancy as compared with a control group of head and neck cancer patients who were less mutagen sensitive.
 - Prospective studies of head and neck cancer patients have shown that mutagen sensitivity was a significant predictor of risk for developing a second primary malignancy and can then be used as a “marker” for second primary malignancies.
 - Second primary malignancy:
 - In spite of recent advances in the therapeutic management of the head and neck cancer patient, overall survival of these patients has not substantially improved.
 - Prime reason for absence of improved overall survival of the head and neck cancer patient is their increased risk of developing a second primary malignancy.
 - As compared with standard population, head and neck cancer patient is at greater risk (10 to 30 times) of developing a second primary malignancy, with the frequency varying from less than 5% to as high as 36%, with many studies in the 15% to 25% range.
 - Criteria used in defining multiple primary carcinomas include that:
 - Tumors be separate and distinct (at least 2 cm apart) without any dysplasia in the intervening mucosa and that the second primary tumor does not represent a metastasis or recurrent tumor
 - Diagnosis of a second primary tumor such as in the lung includes the presence of a solitary lesion that is histologically distinct from primary tumor
 - Second primary malignancies occurring within a 6-month period from the discovery of primary cancer are termed synchronous cancer, whereas second primary malignancy that occurs after the 6-month period from the discovery of the first tumor are referred to as metachronous cancer.
 - Most second malignancies develop in other upper aerodigestive tract mucosal sites:
 - Non-head and neck sites in which second malignancies develop include the lungs, esophagus, and bowel.
 - Most often, histology of second primary malignant neoplasm is a squamous carcinoma, but other histologic types such as adenocarcinomas may occur.

- Some of the more recently defined high-grade variants of squamous cell carcinoma (e.g., basaloid squamous cell carcinoma) are notorious for the presence of multiple concurrent primary tumors in mucosal sites of the head and neck at the time of initial presentation; factors that may play a significant role in development of a second malignancy include the site of the original primary cancer, age of the patient, size of the primary tumor, status of regional lymph nodes, and use of tobacco and alcohol:
 - Head and neck second malignancies are more likely to develop when the primary cancer is in the oral cavity, hypopharynx, or oropharynx than if the index tumor is of laryngeal origin.
 - Patients who developed their tumors prior to 60 years of age may be at greater risk of developing a second primary malignancy.
 - Patients with lower stage index tumors (T1 and T2) and patients who had no nodal metastasis (N0) at the presentation of their index tumor were more likely to develop a second malignancy than patients with higher stage index tumors and patients who did have nodal metastasis at the presentation of their index tumor.
 - Patients with index tumors of the head and neck who smoke tobacco (greater than 20 pack-years) and consume alcohol were at significant increased risk of developing a second malignancy than head and neck cancer patients who did not.
 - Microsatellite instability and smoking after treatment of the index tumor correlate with increased risk of multiple malignancies.
 - During the HPV era, second primary malignancy risk associated with oropharyngeal SCC has declined to lowest risk level of any subsite.
- Survival rates after the second cancer are influenced by the site of the second malignancy and persistent use and abuse of tobacco and alcohol:
 - Second malignancies of the lung and esophagus portend a significantly worse prognosis than second malignancies of other head and neck sites, with 5-year survival rates from the diagnosis of the second malignancy of 2% (for lung) and 3% (for esophagus) versus 20% for second head and neck malignancies.
 - Continued use of tobacco and alcohol also adversely affected survival rates, with 5-year survival rates of 5% for smokers versus 20% for nonsmokers, and 6% for drinkers versus 27% for nondrinkers.
 - Despite a modicum of increased overall survival in some groups, the development of a second malignancy is almost always fatal.
- Site of the second malignancy differs for different index tumors:
 - Development of a second primary head and neck or esophageal malignancy is more prevalent after oral cavity and pharyngeal index tumors.
 - Development of a second primary tumor of the lung is most common after a laryngeal index tumor.
- Shared mucosal susceptibility between index tumor and second malignancy is suggested as accounting for phenomenon of second primary malignancies:
 - A common “digestive tract axis” is shared between oral cavity, pharynx, and the esophagus, whereas the larynx and lung share a common “respiratory tract axis.”
 - Shared mucosal susceptibility is variation on “field cancerization” concept (see previous), highlighting importance of carcinogen activation of an entire exposed mucosa
 - Normal mucosa surrounding preinvasive and microinvasive HNSCCs share common genetic aberrations with tumor supporting the concept that second primary tumors represent extensions of initial tumor clone.
- Increased glutathione S-transferase (GST) expression, a carcinogen-detoxifying enzyme, may represent a possible “marker” for development of secondary malignancies in the head and neck cancer patient:
 - In patients with primary oral squamous cell carcinoma who developed a second primary head and neck malignancy, there is increased expression of GST in the normal tissues in direct vicinity of the index tumor in comparison with matched controls.
 - Increased GST is believed to have predictive value for the development of a second primary tumor.
 - More recently, findings suggest that copy number variant (CNV) and promoter genetic variants in glutathione S-transferase Mu class 1 (GSTM1) and promoter haplotype are better predictors of recurrence/second primary tumors of head and neck cancer than just measuring the presence/absence of GSTM1.
- Genetic variants in the PI3K/PTEN/AKT/mTOR pathway could serve as biomarkers to identify which patients are at high risk of recurrence/second primary tumor while also predicting response to 13-cRA chemoprevention for HNSCC patients.
- A critical issue for the otolaryngologist in the evaluation and planned treatment of the head and neck cancer patient is to be aware of the

possibility that the patient has or will develop a second primary malignancy:

- Diagnosis of a primary head and neck cancer should initiate panendoscopic evaluation of the entire upper aerodigestive tract, as well as the lower aerodigestive tract and esophagus to exclude the possibility of a synchronous second primary cancer, with vigilant follow-up care given the possibility of developing a metachronous cancer.
 - Results of these findings may ultimately affect the diagnostic approach, treatment protocol, and prognostic impact for that patient.
 - Development of a second primary malignancy is in all likelihood a multifactorial process combining genetic and environmental risks.
 - Development of a second primary cancer may potentially be predictive on the basis of sophisticated molecular biologic assessment (e.g., DNA microarrays).
 - Prognostic indicators in HNSCC include:
 - Status of surgical resection margins:
 - Arguably, single most important parameter in determining local recurrence in HNSCC presence of residual carcinoma at surgical resection margins
 - Margin status and local recurrence are site dependent and assist in explaining why surgeons are more apt to accept nearer margins for laryngeal carcinoma (free margins up to 2 mm) but require wider margins (5 to 10 mm) for carcinomas of extralaryngeal mucosal sites.
 - Larynx perhaps is an outlier in regard to positive margins and local recurrence:
 - As compared to extralaryngeal mucosal sites, patients with primary laryngeal squamous cell carcinoma with positive surgical margins have a significantly lower incidence of local recurrence.
 - Factors that may contribute to the lower incidence of local recurrences in laryngeal squamous cell carcinoma with positive margins supporting organ sparing (conservative) laryngectomy may include:
 - ◻ These patients have early stage carcinoma associated with a more favorable prognosis.
 - ◻ Submucosa of the glottic region has (quantitatively) less lymph-vascular spaces, thereby decreasing the incidence of spread and lowering the incidence of locoregional failure.
 - Among the extralaryngeal sites with significant recurrence rates after negative surgical margin determination include the oral cavity and pharynx:
 - A factor that contributes to the recurrence rates of pharyngeal and oral cavity carcinomas in the face of negative surgical margins is the tendency for submucosal spread by these carcinomas.
 - Intraoral sites with negative margins but significant recurrence rates include the palate, tonsil, buccal mucosa, tongue, gingiva, floor of mouth, and lip.
 - Absence of positive margins does not guarantee local control of disease nor is it a reliable guide to the biologic behavior of a tumor.
 - In general, the lower the clinical stage and/or pathologic class the better the ability to achieve local control and the overall better survival rates.
 - Factors that may affect whether a margin is positive or negative and in prognosis (control of disease) include:
 - Clinical stage:
 - ◻ Patients with positive margins more often have stage III and IV operable tumors, have a significantly higher rate of local failure, distant failure
- Resection margin status alone is not an independent predictor of local recurrence nor should resection margin status alone be used as the sole variable in deciding whether adjunctive radiation therapy is required; rather the need to give adjunctive radiation is suggested to be based on the following parameters:
 - Clinical stage:
 - Patients with positive margins more often have stage III and IV operable tumors, have a significantly higher rate of local failure, distant failure
 - Tumor dimensions:
 - Tumor size and extent of invasion determine clinical and pathologic T stage for HNSCC:
 - ◻ T stage has traditionally been considered an important risk factor for presence of concomitant nodal metastasis, local recurrence, and poor survival.
 - Malignancy grading and risk stratification:
 - Histologic risk assessment that includes score based on worst pattern of invasion. Patterns of invasion include:
 - ◻ Grade I = invasion in broad pushing front
 - ◻ Grade II = invasion in “finger-like” broad pushing pattern or separate large tumor islands
 - ◻ Grade III = invasive tumor islands of tumor at periphery greater than 15 cells/island
 - ◻ Grade IV = invasive tumor islands of tumor at periphery smaller than 15 cells/island or

strands of tumor cells in single cell filing pattern regardless of island size

- Grade V = satellites of dispersed tumor infiltrates of any size with 1 mm or greater distance of intervening normal (nonfibrotic) tissue at the tumor-host interface
- Histologic assessment results in stratification of patients into low-risk, intermediate-risk, and high-risk categories that define recommendations for adjuvant radiotherapy (Table 6-3):
 - Carcinomas invading with grade 3 or 4 patterns are associated with an increase in

nodal and distant metastasis and a significant decrease in survival.

- Grade 3 and 4 invasive patterns tend to be larger tumors (higher T stage).

NOTE: In practice, the histologic assessment of the patterns of invasion is not considered a standard of practice, and most pathologists do not render such an evaluation on intraoperative consultation or even in permanent sections.

- Perineural invasion (PNI) (Fig. 6-45):
 - Presence of PNI represents an important predictor of poor prognosis.
 - Presence of PNI associated with higher risk of metastasis to regional lymph nodes

TABLE 6-3 Risk Assessment for Oral Squamous Cell Carcinoma

Histologic Variable	0	1	3
Perineural invasion	None	Small nerves	Large nerves
Lymphocytic response	Continuous band	Large patches	Little to none
Worst pattern of invasion at interface*	1, 2, or 3	4	5
Risk Score†	Risk for LR	Overall Survival Probability	Adjuvant Treatment with RT
0	Low	Good	No benefit
1 or 2	Intermediate	Intermediate	No benefit
3 to 9	High	Poor	Beneficial regardless of 5-mm margins

Adapted from Brandwein-Gensler M et al: Oral squamous cell carcinoma: histologic risk assessment, but not margin status, is strongly predictive of local disease-free and overall survival, *Am J Surg Pathol* 29:167-178, 2005.

*Patterns of invasion: 1 = invasion in broad pushing front; 2 = invasion in “finger-like” broad pushing pattern or separate large tumor islands; 3 = invasive tumor islands of tumor at periphery greater than 15 cells/island; 4 = invasive tumor islands of tumor at periphery smaller than 15 cells/island or strands of tumor cells in single cell filing pattern regardless of island size; 5 = satellites of dispersed tumor infiltrates of any size with 1 mm or greater distance of intervening normal (nonfibrotic) tissue at the tumor-host interface.

†Sum of all points; *LR*, local recurrence; *RT*, radiotherapy.

Fig. 6-45. Squamous cell carcinoma with perineural invasion.

Lingual invasive squamous cell carcinoma wrapping around peripheral nerves constitutes perineural invasion, also referred to as neurotropism. In (A) carcinoma lies within a few millimeters of the inked resection margin.

- Following definitive treatment, presence of PNI in primary tumor associated with poor local control, regional control, cause-specific survival, and overall survival
- Associated with increase risk of distant metastasis in some but not all studies
- Relationship between PNI and prognosis appears to be independent of nerve diameter (e.g., large named nerve versus small unnamed nerve).
- Despite importance of PNI, percentage of mucosal HNSCCs positive for PNI ranges from 5% to 52%.
- Lymph-vascular invasion (LVI) (Fig. 6-46):
 - Presence of tumor within lymphatic spaces and/or blood vessels (angioinvasion) does not necessarily indicate that metastatic disease is present or will develop:

Fig. 6-46. Lymph-vascular invasion.

Buccal invasive squamous cell carcinoma invading into endothelial-lined (arrows) lumens and is adherent to the vessel wall. Such findings constitute lymph-vascular invasion.

- Several studies have demonstrated a statistical correlation between the identification of lymph-vascular space invasion and nodal metastasis.

- Lymph node metastasis (Fig. 6-47):
 - In general, cervical nodal metastasis is considered an adverse prognostic finding.
 - For head and neck metastatic carcinoma to lymph nodes, several factors may have prognostic significance, including the presence of extracapsular extension by the tumor, site of nodal metastasis, number of lymph nodes with

Fig. 6-47. Extranodal extension.

Laryngeal squamous cell carcinoma metastatic to a cervical neck lymph node with extranodal extension. **A**, At low magnification residual lymph node parenchyma (arrowheads) can be seen but most of the node architecture is effaced by the metastatic carcinoma, the latter with extensive invasion into perinodal soft tissues (arrows). **B**, Higher magnification shows the presence of moderately well-differentiated squamous cell carcinoma within perinodal adipose tissue.

metastatic disease, node fixation, and tissue response to metastatic tumor.

- Metastatic carcinoma confined to within the lymph node has survival rates similar to histologically negative lymph nodes.
 - Presence of nodal metastasis with extension of the tumor outside the capsular confines of the lymph node and into perithyroidal soft tissues (extranodal extension [ENE]) is generally considered an adverse finding associated with increased risk of recurrent disease, increased risk of distant metastasis, and reduction in long-term survival by up to 50%.
 - ENE is further subdivided based on whether the extracapsular spread is found microscopically or whether this feature was evident by gross examination:
 - Macroscopic ENE associated with an even greater risk of recurrent disease than by microscopic determination alone
 - Lymph nodes measuring more than 3 cm demonstrate a greater than 75% incidence of ENE.
 - Documentation in the surgical pathology report should include the presence or absence of nodal metastasis and if nodal metastasis is present whether there is or is not extracapsular spread.
 - Presence of ENE is an indicator for adjuvant therapy (radiation or chemotherapy).
 - Presence of lymph node and/or distant metastasis is correlated with increased morbidity and mortality in association with most malignancies, including HNSCC (a notable exception would be thyroid papillary carcinoma, which generally is an indolent tumor even in the presence of nodal metastasis).
 - Site of metastatic disease may affect overall prognosis:
 - Patients with a nodal metastasis to the lower neck area have a worse prognosis than patients in whom the metastatic deposits are limited to upper neck.
 - Abnormal retropharyngeal adenopathy, as determined by radiographic assessment (e.g., CT, MRI, PET), is an adverse predictor of outcome in squamous cell carcinoma of the head and neck:
 - Rates of neck relapse and distant metastasis are significantly higher with retropharyngeal adenopathy.
 - Rates of 5-year relapse-free survival and absolute survival are significantly lower with retropharyngeal adenopathy.
 - Size of largest positive lymph node may serve as clinical predictor of outcome but conflict-
- ing information in the literature affirming and disproving size
- Distant metastasis:
 - Distant metastatic tumor from a head and neck squamous carcinoma carries ominous clinical import, generally heralding the demise of the patient over relatively short periods of time despite all attempts at controlling disease.
 - Distant metastasis by hematogenous spread to visceral sites from a head and neck squamous carcinoma most commonly includes spread to the lungs, liver, and bone.
 - Among the factors that may be associated with distant metastatic tumor are the histologic type of cancer, tumor size, and the status of cervical lymph node involvement.
 - Several of the more recently described high-grade variants of squamous carcinoma, including the basaloid squamous cell carcinoma and adenosquamous carcinoma, often present as large tumors that are deeply invasive, associated with nodal and distant metastasis.
 - Reason for this aggressive behavior at presentation is not completely understood.
 - Increased tumor size (T stage) and cervical node involvement (N stage) have been shown to have a high incidence of distant metastases.
 - In addition to N stage, the number of lymph nodes involved, the number of lymphatic chains involved, and the presence of extranodal extension spread have been shown to be associated with an increased incidence of distant metastasis.
 - When three or more lymph nodes have metastatic disease the distant recurrence-free survival is reduced to 41% as compared with 84% when one lymph node was involved and 57% when two lymph nodes were involved.
 - When two or more lymphatic chains contained metastatic tumor, the distant recurrence-free survival is reduced to 40% as compared with 74% when one lymphatic chain was involved.
 - Nodal status has been viewed as a significant prognostic factor in the presence of distant metastases such that the presence of tumor in cervical lymph nodes represents a positive correlation with the development of distant metastases.
 - Distant metastasis occurs most frequently in patients with residual or recurrent disease in the neck.
 - Skin involvement by HNSCC is uncommon:
 - Usually is an indication of advanced or recurrent disease
 - Has adverse prognostic implications

- Presence of direct cutaneous extension from a mucosal SCC is associated with a mean survival of 7 months, whereas intra-dermal lymphatic spread carried a mean survival of 3 months.
- Involvement of facial skin had an overall better prognosis than when there was involvement of neck skin, with 12-month and 3-month median survival, respectively.
- Invasion of soft tissue structures (Fig. 6-48):
 - Surgical margins of resection may include all soft tissue components, including adipose tissue, skeletal muscle, bone, and neural structures.
 - For laryngeal carcinomas invasion of the cartilaginous framework is considered to represent an adverse prognostic finding:
 - Cartilage invasion is most frequently seen in association with transglottic carcinomas.
 - Invasion of cartilage often occurs in cartilage that has undergone ossification.
 - Hyaline cartilage believed to be resistant to invasive cancer
 - In the larynx, there is preferential invasion of squamous carcinoma into ossified cartilage as compared with nonossified cartilage:
 - However, this is not universally held to be true because there may be extensive invasion of laryngeal squamous carcinoma into nonossified cricoid and thyroid cartilage.
 - An increased incidence of nodal metastasis and mortality is associated with the presence of cartilage invasion.
 - Presence of neurotropism in HNSCC should be considered an adverse finding in head and neck malignancies indicative of the tumor's biologic aggressiveness as determined by an

Fig. 6-48. Invasive squamous cell carcinoma.

Floor-of-mouth invasive squamous cell carcinoma showing (A) osseous invasion and (B) invasion into skeletal muscle. C, Infected osteoradionecrosis includes necrotic bone and associated neutrophilic infiltrate containing bacterial colonies consistent with *Actinomyces* species. D, Squamous epithelium resulting from fistula from oral cavity mucosa is directly applied to bone comprised of bland-appearing squamous cells lacking cytomorphic features of carcinoma.

- increased incidence of local recurrence, nodal metastasis, and/or decreased patient survival.
- Extension into soft tissue structures such as fat and muscle or cartilaginous and osseous invasion by HNSCC in general is indicative of a higher clinical stage tumor associated with a higher incidence of nodal metastasis.
 - Invasion and destruction of bone by cancer are thought to be performed by osteoclasts mediated by prostaglandins rather than by the direct action of the invasive cancer.
- For oral cavity carcinomas, presence of dentition significantly influences nerve-related spread:
- A fourfold increase in cancer spread related to the inferior alveolar nerve in edentulous, nonirradiated mandibles as opposed to partially dentate, nonirradiated mandibles and nerve involvement is associated with extensive spread of carcinoma in the medullary parts of the bone.
 - Bone, in particular the osseous margins of resection of the mandibular region, pose an especially significant issue in regard to carcinomas of the alveolar ridge, floor of mouth, lower buccal sulcus, and lower retromolar region:
 - Carcinomas of these sites are among those with the highest rate of recurrence.
 - Evaluation of mandibular bone for the presence and extent of involvement is a key determinant in patient management. Methods of evaluating for osseous involvement include preoperative radiologic assessment; gross inspection; frozen section or imprint evaluation of bone from the resected osseous stump; and frozen section of adherent soft tissues.
 - Clinical determination of mandibular involvement is not reliable because one third of histologically proven carcinomatous invasion of the mandible showed no clinical indication of (preoperative) bone involvement.
 - Spread of oral carcinoma to mandible typically occurs by direct invasion rather than by metastasis, lymph-vascular space spread, or via nerves.
 - Spread of carcinoma is nearly always through cancellous bone and its marrow spaces.
 - Size of the carcinoma (T stage) does not appear to influence the incidence of bone involvement but proximity to bone does.
 - Must be differentiated from infected osteoradionecrosis (IORN) with pseudocarcinomatous hyperplasia (PCH) or pseudoepitheliomatous hyperplasia (PEH):
 - Actinomycosis of the jaws is a rare disease described in patients with IORN and bisphosphonate-associated osteonecrosis (BON)
 - Typical scenario for IORN is patient with oral squamous cell carcinoma treated with radiation who develops osteoradionecrosis characterized by:
 - Fragments of necrotic bone intimately associated with bacterial colonies showing findings consistent with *Actinomyces* as well as an associated neutrophilic cell infiltrate
 - Benign squamous epithelium representing PCH or PEH may be present:
 - Given fact that gnathic bone is close to epithelial structures of both gum and periodontium, PCH/PEH may occur strongly associated with occurrence of fistula
 - Mandibular involvement much more common occurrence than involvement of maxilla
 - Critical issue is whether epithelium represents PCH/PEH or invasive carcinoma
 - Histologic features favoring PCH/PEH include:
 - Fragments of squamous epithelium identified in medullary space directly applied to necrotic bone trabeculae predominantly comprised of rather bland appearing cells lacking histologic features of squamous cell carcinoma
 - Often characterized by more mature epithelial layer covering bone trabeculae without intervening stroma, and basal type epithelial layer surrounding a central fibrovascular core
 - No cytomorphic features of malignancy
 - Invasive squamous cell carcinoma tends to include tumoral islands within centromedullary area surrounded by stroma with cytomorphic features of malignancy
 - Host immunologic response:
 - Host response to cancer as seen by the presence of a peritumoral lymphocytic infiltrate (PLI) may portend a better prognosis than those cases in which there is an absence of a significant inflammatory cell response.

- Tumor angiogenesis:
 - Tumor angiogenesis or neovascularization is defined as the ingrowth and development of new capillary vessels, representing an important factor in solid tumor growth.
 - Tumor angiogenesis permits rapid expansion of primary invasive carcinomas (e.g., skin, breast, lung, and prostate), correlating with the presence of metastatic disease and decreased survival rates.
 - Tumor angiogenesis can be measured by immunohistochemical staining of the blood vessels in a tumor and determining its vascularity (microvessel counts).
 - Studies to date for head and neck carcinomas have not been found to be useful prognostic marker in determining the frequency of local recurrence, metastatic disease or survival in head and neck cancer patients; these results sharply contrast with invasive cancers of other organ systems.
- Factors related to patient's general medical condition:
 - Comorbidity:
 - Refers to presence of other diseases, illnesses, or conditions not directly related to index cancer that may influence care of cancer patients, selection of treatment modalities, evaluation of treatment effectiveness
 - Nutritional status:
 - Strong evidence for association between malnutrition and increased risk of postoperative complications
 - Anemia:
 - Commonly occurs in patients with head and neck cancer
 - Due to a number of causes including comorbid illness, intraoperative blood loss, toxicity from chemotherapy and/or radiation therapy, and malignancy-associated anemia of chronic disease
 - Thought to enhance radioresistance via enhancing tumor hypoxia
 - Correlates with inferior local-regional control among patients treated with surgery alone, suggesting anemia may influence outcome independent of its influence on hypoxic resistance
 - Karnofsky performance status (KPS)
 - **Definition:** Attempt to quantify cancer patient's general well-being and activities of daily life and is a measure used:
 - To determine whether cancer patients can receive chemotherapy
 - To determine whether dose adjustment is necessary
 - As a measure for the required intensity of palliative care
 - In oncologic randomized controlled trials as a measure of quality of life
 - Provides uniform, objective assessment of an individual's functional status
 - Reliable independent predictor of survival outcome for patients with solid tumors
 - Required baseline assessment in clinical protocols in head and neck cancers
 - Scale is in 10-point increments from 0 (dead) to 100 (normal, no complaints, no evidence of disease):
 - 100: normal, no complains, no evidence of disease
 - 90: Able to carry on normal activity; minor signs or symptoms of disease
 - 80: Able to carry on normal activity with effort; some signs of symptoms of disease
 - 70: Cares for self; unable to carry on normal activity or do active work
 - 60: Requires occasional assistance but is able to care for most of own needs
 - 50: Requires considerable assistance and frequent medical care
 - 40: Disabled; requires special care and assistance
 - Diagnosis and treatment of depression may also aid in symptom control and improved quality of life.

SQUAMOUS CELL CARCINOMA (SCC) OF THE ORAL CAVITY

General Considerations

- Oral SCC represents approximately 5% of all malignant neoplasms in men and approximately 2% of all malignant neoplasms in women.
- Squamous cell carcinoma (SCC) or variants thereof are the most common malignant neoplasms, accounting for approximately 95% of all malignant neoplasms of the oral cavity.
- More common in men than in women:
 - Male gender predilection is historically related to greater use/abuse of tobacco and alcohol by men; however, with greater use of tobacco and alcohol by women, gender predilection may alter in the next few decades.
- Occurs over a wide age range but most common in the fifth to ninth decades of life; considered unusual prior to 40 years of age:
 - A definitive subset of patients developing squamous cell carcinoma are under 40 years of age:

- May include men and women but approximately 50% are women
- Young women developing lingual carcinoma are noteworthy for an absence of history of tobacco and alcohol use/abuse.
- To date, no definitive known predisposing risk factors but likely related to genetic susceptibility
- Most common sites of occurrence in the oral cavity in descending order of frequency are:
 - Lower lip, tongue, floor of mouth, gingival, palate, tonsil, upper lip, buccal mucosa, uvula
- Causative factors linked to the development of oral squamous carcinoma include:
 - Tobacco and alcohol: combined effect of tobacco and alcohol in development of SCC is well established, is multiplicative, and represents independent risk factors:
 - Tobacco:
 - Tobacco use/abuse includes smoking and chewing (smokeless tobacco).
 - Major cause of oral squamous cell carcinoma
 - Alcohol:
 - Alcohol potentiates tobacco-related carcinogenesis.
 - Oncogenic viruses:
 - Human papillomavirus (HPV) and Epstein-Barr virus (EBV):
 - Found in small percentage of oral squamous cell carcinomas
 - Sunlight (for carcinoma of the lip)
 - Nutritional factors include:
 - Plummer-Vinson syndrome (chronic iron deficiency)
 - Cirrhosis
 - Immunocompromised states:
 - Link of gingival carcinoma to immune-related disorders, including HIV/AIDS patients and host-versus-graft disease after marrow transplants, suggests an etiologic role.
 - Effect may be as a potentiator in conjunction with other risk factors (e.g., oncoviruses)
 - Conditions potentially linked to the development of oral carcinoma include:
 - Syphilis
 - Lichen planus
 - Submucous fibrosis
 - Sideropenic dysphagia
 - Environmental factors include:
 - Exposure to nickel, leather tanning products, formaldehyde
 - Above exposures may not be directly linked to development of squamous carcinoma but greater use of tobacco and alcohol products by workers with the above cited exposures may represent the greater risk factors.
- Other factors include:
 - Trauma and dental irritation
 - Poor oral hygiene
- Common sites in the oral cavity for the development of SCC include:
 - Tongue: lateral and ventral surfaces
 - Floor of mouth
 - Alveolar trigone
 - Buccal mucosa
 - Gingival and edentulous alveolar ridges
- Less common primary sites in the oral cavity for the development of SCC include:
 - Hard palate and dorsal aspect of the tongue:
 - Involvement of these sites most often occurs from extension of the carcinoma from adjacent sites.
- Signs and symptoms of oral SCC vary, depending on size and location of the lesion, and include:
 - Small lesions may be asymptomatic or present with minimal findings and vague symptoms.
 - Leukoplakia, erythroplakia, or speckled leukoplakia (mixed leukoplakic and erythroplakic)
 - Mass lesion; ulceration; pain (local and referred); difficulty swallowing, speaking, chewing, and opening the mouth; bleeding; and weight loss
 - Enlarged neck nodes (appearing as a neck mass) may be present in conjunction with an identifiable intraoral mass or in the absence of an intraoral mass.
 - In advanced cancers there may be:
 - Invasion into adjacent structures such as bone, muscle, and skin and may result in orocutaneous fistulas
 - Cachexia, severe anemia, and bleeding
- Radiology:
 - Radiographic imaging, including CT scan, MRI, and PET scan, supplements the clinical evaluation of oral SCC.
 - Imaging studies assist in the assessment of:
 - Local extent of the primary tumor
 - Regional nodal disease
- Histology:
 - Majority of oral SCC are of the keratinizing (conventional) type
 - Histologic grade includes variations of well-, moderately and poorly differentiated SCC
 - Associated premalignant surface epithelial changes often are identified:
 - Carcinoma in situ (CIS): cellular dysplasia involving the entire thickness of the mucosa without compromise of the basement membrane; the dysplasia may extend into adjacent seromucous glands and is still considered an in situ lesion

- Microinvasive carcinoma: malignant cells that have penetrated the basement membrane and infiltrate into the superficial compartment of the lamina propria
- For a more complete discussion and illustrations, see Section 5, Larynx.
- Variants of conventional SCC may also be identified, including:
 - Verrucous carcinoma
 - Spindle cell squamous carcinoma
 - Basaloid squamous cell carcinoma
 - Adenosquamous carcinoma
 - Lymphoepithelioma-like carcinoma
 - Others
- Treatment:
 - Primary therapy for oral SCC depends on several factors, including those related to the primary tumor, those related to the patient, and those related to the treatment delivery team:
 - Clinical stage:
 - Early stage cancers (stage I, II) include surgery, radiotherapy, or combination.
 - More advanced cancers (stage III, IV) include combinations of surgery, radiation, and chemotherapy.
 - Radiotherapy: the basis of radiation therapy for cancer treatment is due to the ability of ionizing radiation to cause damage to DNA strands, either directly fragmenting the molecule or indirectly creating an area of ionized free radicals in the vicinity of the coiled chromatin, thereby impairing the capacity of cells to repair or regenerate; radiation can essentially be delivered in two ways:
 - Teletherapy: delivery of ionizing radiation from a remote distance
 - Brachytherapy: delivery of ionizing radiation at a site close to (e.g., within a cavity or intracavitary) or within the target organ or tissue (interstitial)
 - Chemotherapy is the use of chemical (anticancer) agents to treat or control disease by destroying cancer cells:
 - Induction chemotherapy is the first stage in treatment where chemotherapy is used to reduce the number of cancer cells.
 - Neoadjuvant chemotherapy is the term used for the administration of chemotherapy prior to surgery and is generally designed to decrease the size of the tumor prior to resection:
 - In general, neoadjuvant chemotherapy can improve the chances for complete surgical resection or decrease the overall surgery needed.

- Chemical agents most commonly used neoadjuvantly include cisplatin and 5-fluorouracil.

Surgical Specimens

- Surgical resection for oral cavity cancers are among the most radical procedures, resulting in extensive cosmetic and functional deformities associated with significant quality of life issues.
- Postoperative rehabilitation of functional status includes speech, swallowing, and breathing.
- Among the variety of surgical procedures used in the treatment of oral cavity cancers include:
 - Glossectomy:
 - Partial or complete surgical removal of the tongue
 - Mandibulectomy:
 - Marginal mandibulectomy
 - Mandible sparing procedure
 - Indicated:
 - To obtain satisfactory three-dimensional margins around the primary tumor
 - When the primary tumor approximates the mandible
 - When minimal cortical erosion or minimal erosion of the alveolar process of the mandible is present
 - Not indicated:
 - In the presence of massive soft tissue disease or of gross invasion into the cancellous part of the mandible
 - In patients with previous irradiated edentulous mandibles
 - Patients with a pipe-stem mandible
 - Segmental mandibulectomy:
 - Required in the presence of gross invasion of the cancellous part of the mandible or invasion of the alveolar canal by perineural spread
 - Required for all primary tumors of the mandible
 - Mandibulotomy or mandibular osteotomy:
 - Mandible-sparing procedure
 - Designed to gain access to the oral cavity or oropharynx for resection of primary tumors not accessible through an open mouth or through the lower lip cheek-flap approach
 - May be approached laterally, in the midline or paramedian
 - Composite resection
 - Resection of part of mandibular alveolar ridge (marginal or segmental mandibulectomy) often along with the floor of mouth and a part of the tongue

- Generally used for advanced squamous cell carcinoma, although occasionally used for osteoradionecrosis after complications of prior irradiation or for other malignancies such as osteosarcoma
- Incidence of developing a second primary tumor in patients with oral carcinoma is significantly increased:
 - Patients with squamous cell carcinoma of the upper aerodigestive tract are at significant increased risk of developing another mucosal squamous cell carcinoma.
 - For a more complete discussion on second primary tumors and field cancerization see previously in this section.
- Prognosis is influenced by a variety of factors, the most important being the clinical stage of the neoplasm:
 - Approximately 75% of intraoral SCC are advanced stage tumors (i.e., stage III, IV) at diagnosis, negatively affecting prognosis.
- TNM staging for oral cavity cancers, including the lip, is detailed in [Table 6-4](#).

NOTE: Staging of oral cavity tumors applies to epithelial neoplasms and not to nonepithelial tumors, including mesenchymal, hematolymphoid, melanocytic, neuroendocrine, osseous, and cartilaginous tumors.

- Owing to differences in the clinicopathologic and prognostic findings, site-specific oral squamous carcinoma is addressed separately.

Squamous Cell Carcinoma (SCC) of the Lip ([Fig. 6-49](#))

- Accounts for approximately 25% to 30% of all oral SCCs
- More common in men than in women; most frequently identified in the fifth through eighth decades of life:
 - Less common occurrence in women may relate to protective effect of lipstick use and less outdoor exposure.
- More common in Caucasians; rare in blacks and dark-skinned individuals
- More than 90% occur on lower lip; less than 10% occur on upper lip.
- Most common site of occurrence is the vermilion border (exposed mucosa between the mucocutaneous junction and the point of contact of the lips) lateral to the midline.
- Clinical presentation varies depending on stage of cancer:
 - Majority of lip SCCs are superficial, representing Tis, T1, and T2 neoplasms.

Fig. 6-49. Squamous cell carcinoma of the lip.

- Early lesions:
 - White, red, or mixed-appearing thickening
 - Non-healing fissure or erosion
- More advanced lesions:
 - Usually ulcerated and indurated lesion
- Carcinomas of the lower lip, unlike those of upper lip, tend to grow slowly.
- Some carcinomas have propensity to involve nerves, causing numbness, pain:
 - Neurotropism may occur even in the presence of favorable findings such as better differentiated cancers and lower clinical stage.
- Cause:
 - Chronic exposure to sunlight most important etiologic factor
 - Also linked to pipe smoking
- Pathology:
 - Conventional well to moderately differentiated keratinizing SCC accounts for the majority of these carcinomas.
 - Other histologic variants of SCC may occur including (but not limited to) spindle cell squamous carcinoma and adenoid SCC.

TABLE 6-4 TNM Classification: Lip and Oral Carcinomas

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor 2 cm or less in greatest dimension
T2	Tumor more than 2 cm but not more than 4 cm in greatest dimension
T3	Tumor more than 4 cm in greatest dimension
T4a	(Lip) Moderately advanced local disease: tumor invades through cortical bone, inferior alveolar nerve, floor of mouth, or skin of face (i.e., chin or nose)
T4a	(Oral cavity) Moderately advanced local disease: tumor invades adjacent structures (e.g., through cortical bone, into deep [extrinsic] muscles of tongue, genioglossus, hyoglossus, palatoglossus and styloglossus), maxillary sinus, skin of face
T4b	Very advanced local disease: tumor invades masticator space, pterygoid plates, or skull base and/or encases internal carotid
Note: Superficial erosion alone of bone/tooth socket by gingival primary is not sufficient to classify tumor as T4	
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
N2	Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension; or in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension; or in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N2a	Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension
N2b	Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension
N2c	Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N3	Metastasis in a lymph node more than 6 cm in greatest dimension
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis
Staging Oral Cancers	
Stage 0	TisN0M0
Stage I	T1N0M0
Stage II	T2N0M0
Stage III	T3N0M0 T1N1M0 T2N1M0 T3N1M0
Stage IVA	T4aN0M0 T4aN1M0 T1N2M0 T2N2M0 T3N2M0 T4aN2M0
Stage IVB	AnyTN3M0 T4bAnyNM0
Stage IVC	AntTAnyNM1

- Complete surgical excision and/or radiotherapy are preferred treatments.
- Brachytherapy effective in treatment, with local control rates of >90% for T1-T2 lower lip cancers
- Lymph node metastasis:
 - Regional lymph node metastases occur in only 10%.
 - Elective neck dissection warranted for higher grade carcinomas, larger tumors (T2 or greater and for thicker lesions >1 cm), clinically positive nodes, carcinomas at the oral commissure, and locally recurrent tumors
 - Metastases occur late in the disease course, involving the submental and submandibular lymph nodes are primary echelon drainage pathway:
 - Drainage may go to intraparotid or jugular chain lymph nodes.
- SCCs of lower lip are slow growing but will eventually spread to adjacent structures.
- SCCs of upper lip tend to metastasize to regional lymph nodes (periparotid) relatively early in the course of disease.
- Overall 5-year survival rate is:
 - Lower lip greater than 75%
 - Upper lip 34% to 58%
- Factors influencing prognosis include:
 - Tumor size:
 - Smaller tumors (i.e., T1 and T2) in the absence of clinically detectable nodal metastasis:
 - Cure rates of more than 90%
 - Correlated with early detection
 - Larger tumors (i.e., T3, T4) in the absence of clinically detectable nodal metastasis:
 - Survival rate of 30% to 50%
 - Presence of metastatic disease:
 - Regional nodal metastasis associated with 50% decrease in overall 5-year survival
 - Neurotropism:
 - Presence of perineural or intraneural invasion is associated with decrease survival rates.
 - Other important adverse prognostic findings include:
 - Tumor thickness/depth of invasion
 - Angioinvasion
 - Histologic grade of the tumor:
 - Grade I: 3-year cure rate of 95%
 - Grade II: 3-year cure rate of 46%
 - Grade III: 3-year cure rate of 38%
 - Correlates less well (as compared with tumor size, nodal metastasis) to patient outcome but pattern of invasion correlates with predicting clinical course:
 - Less differentiated carcinomas associated with worse prognosis linked to greater tendency to regional nodal metastasis

Fig. 6-50. Carcinoma of the oral (mobile) tongue.

Squamous cell carcinoma of the lateral tongue.

Squamous Cell Carcinoma of the Oral Tongue (Fig. 6-50)

- Accounts for approximately 25% of all oral carcinomas; excluding the lips, lingual carcinomas compose greater than 50% of all intraoral carcinomas, representing the most common site of oral SCC.
- More common in men than women; most frequently identified in the fifth through ninth decades of life; considered unusual prior to 40 years of age
- A definitive subset of patients with oral tongue SCC are under 40 to 45 years (SCC of oral tongue in young individuals):
 - May include men and women but higher percentage occurs in women
 - Young women developing lingual carcinoma are noteworthy for an absence of history of tobacco and alcohol use/abuse.
 - No definitive known predisposing risk factors but may be linked to genetic susceptibility, immune deficiencies, exposure to effects of tobacco via “passive” smoking, and viruses
 - Whole-exome sequencing and copy number analysis found that SCCs of the oral tongue occurring in young individuals (<45 years) were genomically similar to those of older patients (>45 years), and cause for increasing incidence of SCC of the oral tongue in younger patients remains unknown.
- Most common site of occurrence is the lateral and ventral aspect of the anterior two thirds of the tongue, referred to as the mobile portion of the tongue; less common sites include the dorsal aspect and the tip.
- Most common clinical appearance is that of painless ulcerated or exophytic mass:
 - More commonly appears as an erythroplakic than leukoplakic lesion

- Cause:
 - Tobacco and alcohol represent main etiologic factors.
 - Other factors associated with the development of lingual SCC include:
 - Nutritional deficiency (e.g., Plummer-Vinson syndrome, cirrhosis), trauma and dental irritation, and poor oral hygiene
- Pathology:
 - Conventional well- to moderately differentiated keratinizing squamous carcinoma accounts for the majority of the carcinomas.
 - Other histologic variants of squamous carcinoma including (but not limited to) spindle cell and adenoid squamous carcinoma can occur.
- Complete surgical excision alone or in combination with radiotherapy represents the treatment options:
 - Determination of whether surgery alone or in combination with radiation is used depends on several factors, including:
 - Age of the patient
 - Location of the tumor
 - Extent of disease
 - Surgical risk
 - Local excision with margin control for T1 lesions
 - Partial glossectomy for T2 lesions
 - Subtotal or total glossectomy for more advanced lesions
- Preoperative assessment of bone involvement dictates need for mandibulectomy (marginal or segmental):
 - Marginal mandibulectomy for minimal involvement of mandible
 - Segmental mandibulectomy for clearly demonstrable (clinical and/or radiologic) invasion of the mandible
- Management of the neck may include:
 - For patients with clinically positive cervical lymph nodes (N1) at presentation neck dissection is indicated.
 - For more advanced neck metastasis, neck dissection with or without radiotherapy is recommended.
 - Patients with early stage disease with a thickness of <2 mm and/or N0 necks, question of neck dissection is controversial and may include:
 - Observation alone
 - Prophylactic neck dissection and irradiation
 - Factors that may affect whether neck dissection is or is not indicated in early stage cancers (T1 and T2) may include:
 - Pattern of invasion (See [Table 6-3](#))
 - Presence or absence of perineural invasion, lymph-vascular invasion
 - Primary oral tongue carcinomas close to or involving midline have increased risk of

bilateral regional lymph node metastasis; staging neck dissection addresses bilateral nodal basins

- Metastases initially seed to the ipsilateral subdigastric lymph nodes, followed by the submaxillary region, and then to the mid-jugular chain
- Overall 5-year survival rates include:
 - 69% to 90% for Stage I
 - 0 to 26% for Stage II
- Factors negatively influencing prognosis include:
 - Large size of tumor
 - Deeply invasive cancers
 - Infiltrating pattern of advancing front
 - Positive surgical margins
 - Perineural invasion
 - Lymph node metastasis
 - Extranodal extension
 - Presence of distant metastasis:
 - Occurs in 5% to 15%, usually to lung and bone
- Approximately 20% to 30% develop second primary malignancy in the course of their disease.
- Carcinoma of the posterior tongue, also referred to as the base of the tongue, is considered to be oropharyngeal carcinoma see Section 3, Pharynx.

Squamous Cell Carcinoma of the Floor of Mouth ([Fig. 6-51](#))

- Accounts for approximately 20% of all oral carcinomas:
 - Excluding SCC of the lips, floor of mouth SCC is second most common oral malignancy, with lingual SCC being most common.
- More common in men than women; most frequently identified in the sixth to seventh decades of life:

Fig. 6-51. Floor of mouth carcinoma.

Squamous cell carcinoma of the floor of mouth near the frenulum.

- In women tends to occur in younger patients as compared with the same carcinoma in men (usually in the fourth to fifth decades of life).
- Most common site of occurrence is along the anterior aspect of the floor of mouth rather than the posterior portion:
 - Area near the lingual frenum is considered the most common site of occurrence.
- Presentation includes:
 - Ulcerated mass
 - Red (erythroplakic) or white (leukoplakic) mass:
 - More commonly appears as an erythroplakic than leukoplakic lesion
 - With progression of disease symptoms may include:
 - Pain, bleeding, excessive salivation
 - In as high as 75% of cases there is extension of tumor to adjacent structures (e.g., deep soft tissues, tongue) at presentation, resulting in:
 - Motor and sensory deficits include limitation of movement and difficulty speaking.
 - Invasion into bone (i.e., mandible) may occur in approximately 15% to 30% of patients at presentation:
 - Related to proximity of cancer to bone and not necessarily the size of the tumor
 - Invasion usually occurs directly into bone and/or via propagation along nerves and not via hematogenous spread.
 - Bony invasion via nerves occurs greater in edentulous patients as a result of:
 - Disparity in the vertical height of the occlusional border above the mandibular canal
 - Increase in the proximity of the inferior alveolar nerve to the mucosa
 - Cause:
 - Tobacco and alcohol represent main etiologic factors.
 - Pathology:
 - Conventional well- to moderately differentiated squamous carcinoma is the most common histologic type.
 - Complete surgical excision, either alone or in combination with radiotherapy, is preferred treatment:
 - Early stage cancers (I and II) are often managed by either surgery or radiotherapy alone.
 - More advanced cancers (III, IV) often managed by combined surgery and radiotherapy
 - Preoperative assessment of bone involvement dictates need for mandibulectomy (marginal or segmental):
 - Marginal mandibulectomy for minimal involvement of mandible
 - Segmental mandibulectomy for clearly demonstrable (clinical and/or radiologic) invasion of the mandible

- Management of the neck may include:
 - For patients with clinically positive cervical lymph nodes (N1) at presentation, neck dissection is indicated.
 - For more advanced neck metastasis, neck dissection with or without radiotherapy is recommended.
 - For patients with N0 neck, a more aggressive approach may be warranted given reported presence of metastatic disease in significant number of patients who underwent elective neck dissections with floor of mouth cancer.
- Metastases to regional lymph nodes occur to the submandibular triangle and upper jugular chain.
- Overall 5-year survival rates vary from 21% to 66%.
- Factors negatively influencing prognosis include:
 - Large size of tumor
 - Deeply invasive cancers
 - Infiltrating pattern of advancing front
 - Positive surgical margins
 - Perineural invasion
 - Lymph node metastasis
 - Extranodal extension
 - Presence of distant metastasis

Squamous Cell Carcinoma of the Gingiva, Including Retromolar Trigone and Alveolar Mucosa (Fig. 6-52)

- Accounts for approximately 6% of all oral SCC
- More common in men than women; most frequently identified in the sixth through eighth decades of life
- Mandibular gingiva is more commonly affected than the maxillary gingiva:
 - Most common area of gingival carcinoma occurs posterior to canine teeth
 - Edentulous areas are more commonly affected than those areas in which teeth are present.
- Presentation may be relatively nonspecific, including sore throat and referred pain (e.g., otalgia):
 - Owing to nonspecific symptomatology, diagnosis often made at advanced stage
 - Other symptoms may include:
 - Difficulty opening the mouth (trismus)
 - Pain
 - Toothache
 - Bleeding
- Most common clinical appearance is that of ulcerated or exophytic mass:
 - Early cancers of this region may simulate common dental infections, delaying diagnosis.
 - Gingival cancers may extend along periodontal membrane with destruction of supporting bone.

**Fig. 6-52.**

Squamous cell carcinoma of the (A) retromolar trigone and (B) alveolar ridge.

- Due to the small area composing the retromolar trigone, at presentation many SCCs of this region have already spread to adjacent structures, including to the anterior tonsillar pillar, soft palate, buccal mucosa, and floor of mouth.
- As a result of the proximity of the periosteum and underlying bone, cancers of these areas tend to invade bone early in the course of the disease.
- Spread:
 - For gingival cancers may occur:
 - Laterally to cheek, lower lip
 - Medially to hard palate, floor of mouth, ventral tongue
 - For retromolar trigone cancers may spread to:
 - Buccal mucosa, soft palate, mandible
- Cause:
 - Linked to tobacco, alcohol, and poor oral hygiene
 - Snuff dipping implicated as major risk factor for gingival carcinoma
 - Link of gingival carcinoma to immune-related disorders, including HIV/AIDS patients and

host-versus-graft disease after marrow transplants, suggests an etiologic role.

- Pathology:
 - Conventional well- to moderately differentiated keratinizing squamous carcinoma is the most common histologic type.
- Treatment is by surgical excision and/or radiotherapy.
 - T1 and T2 lesions managed by radiation or surgery alone
 - T3 and T4 lesions usually require combined surgery (wide excision) and radiation.
- Mandibulectomy (marginal or segmental) often required:
 - Marginal mandibulectomy for minimal involvement of mandible
 - Segmental mandibulectomy for clearly demonstrable (clinical and/or radiologic) invasion of the mandible
- Management of the neck may include:
 - For patients with clinically positive cervical lymph nodes (N1) at presentation neck dissection is indicated.
 - For more advanced neck metastasis, neck dissection with or without radiotherapy is recommended.
 - For patients with N0 neck a more aggressive approach may be warranted, given presence of metastatic disease in significant number of patients with carcinomas of gingiva, alveolus, and retromolar trigone.
- Metastases to submandibular and jugulodigastric lymph nodes occur from approximately 27% to 60% of patients, especially with carcinomas of the mandibular gingiva.
- Overall 5-year survival rates for gingival and alveolar mucosa cancers include:
 - 55% to 75% for Stage I and II
 - 24% to 44% for more advanced stages
 - Maxillary gingival cancers have better outcomes than mandibular gingival cancers with 5-year cure rates of 53% and 45%, respectively.
- Overall 5-year survival rates for retromolar trigone carcinomas of 31% reported
- Factors influencing prognosis include:
 - Size and site of the tumor
 - Presence or absence of bone involvement
 - Adequacy of surgical margins
 - Presence or absence of metastasis

Squamous Cell Carcinoma of the Buccal Mucosa (Fig. 6-53)

- Incidence varies from 1% to 10% of all oral carcinomas.

Fig. 6-53. Buccal carcinoma.

Squamous cell carcinoma of the buccal mucosa.

- More common in men than women; most frequently occurs in the sixth through eighth decades of life
- Early lesions may present as irregular white plaque (leukoplakia) or red plaque (erythroplakia) or exophytic verrucous lesion.
- More advanced lesions appear as ulcerated/infiltrative or fungating mass:
- Symptoms may include:
 - Early lesions:
 - May be asymptomatic or produce “soreness” of affected area
 - More advanced lesions:
 - Pain, trismus
- Majority of buccal mucosal carcinomas arise inferior to or along a line opposite the plane of occlusion, most often of the middle to posterior portion of the buccal mucosa:
 - Often presents with tumor invasion into the cheek
 - Spread to other adjacent structures frequently occurs and includes jaws (upper and lower), mandibular ramus mucosa, lips, pharynx, tonsil, palate and retromolar trigone and, in advanced disease, to the mandible and maxilla.
- Cause:
 - Linked to tobacco (smoking or chewing), snuff dipping, and alcohol use/abuse
- Pathology:
 - Conventional moderately differentiated keratinizing squamous carcinoma is the most common histologic type; verrucous carcinoma also involves the buccal mucosa.
- Treatment includes surgical excision and/or radiotherapy:
 - Radiation advocated for early cancers
 - Surgery used for infiltrative tumors, including those into deep soft tissues and skeletal muscle:
 - Wide local resection (even for T1 and T2 tumors) associated with high recurrence rates
 - Composite resection
- Locoregional recurrences commonly occur often within 18 months.
- Management of the neck predicated on dismal prognosis for patients with node metastasis:
 - 5-year survival declined from 70% for N0 patients to 49% for N-positive necks:
 - Elective supraomohyoid neck dissection in N0 necks may be considered in these patients with plan to extend area of dissection if clinical nodal disease is discovered during surgery.
- Metastases occur most frequently to the ipsilateral submandibular lymph nodes:
 - Occurs in from 16% to 59% of patients
 - Typically occurs in association with advanced disease
 - Occult metastasis occurs in less than 10% of cases.
 - Posterior located buccal SCCs have a tendency to spread to periparotid and superior deep jugular lymph nodes.
 - Presence of nodal metastasis necessitates neck dissection.
- Overall 5-year survival rates vary from 16% to 89%.
- Factors influencing prognosis include:
 - Tumor size and location
 - Presence or absence of metastasis
 - Tumor thickness (6 mm considered cut-off size)

Squamous Cell Carcinoma of the Hard Palate (Fig. 6-54)

- Among the rarest primary intraoral sites for the development of SCC in North America:
 - Although minor salivary gland malignant tumors occur fairly frequently in this area, squamous cell carcinoma remains most common malignancy affecting the hard palate.
 - In southern India, SCC of the hard palate is among the more common primary site of intraoral carcinoma due to the custom of reverse smoking with the lit end of the cigarette held in the mouth.
 - Hard palate not uncommonly involved by cancers extending from maxillary gingiva and alveolar ridge mucosa
- More common in men than women; most frequently occurs in patients in the seventh decade of life and older

Fig. 6-54. Palate carcinoma.

Squamous cell carcinoma of the hard palate with involvement of the uvula.

- Generally presents as ulcerative lesion with or without associated pain and/or bleeding:
 - May be exophytic or papillary
- May be localized in extent at presentation but approximately one third of cases present with invasion into adjacent structures:
 - Osseous invasion may occur early in the disease course but tends to be present later in the disease course.
 - Occasionally may invade into the sinonasal tract
- Cause:
 - Linked to tobacco and alcohol use/abuse
- Pathology:
 - Conventional moderately differentiated squamous carcinoma is the most common histologic type.
- Treatment includes wide surgical excision and radiotherapy; large soft palate carcinomas can be treated by radiotherapy alone.
- Treatment modalities include surgery or radiation alone:
 - Surgical excision includes wide excision.
 - Large tumors can be treated by radiotherapy alone to preserve functional anatomy.
 - Some authorities advocate not using radiotherapy for hard palate cancers because of the risk involved to the underlying bone (osteoradionecrosis) and to the limited loss of function to this site after surgery.
- Nodal metastasis occurs in approximately 15% to 30%:
 - Occurs most frequently to the submandibular and subdiaphragmatic lymph nodes
 - May be bilateral in up to approximately 5% of patients
 - Neck dissection is performed in the face of overt neck disease.

- Overall 5-year survival rate ranges from 31% to 59%.
- For stages I to IV, 5-year survival rates reported to be 75%, 46%, 36%, and 11%, respectively
- Factors influencing prognosis include:
 - Size of the tumor
 - Presence or absence of metastasis

Variants of Squamous Cell Carcinoma

- Variants of conventional squamous cell carcinoma that may occur in the oral cavity include:
 - Verrucous carcinoma (Fig. 6-55)
 - Papillary squamous cell carcinoma
 - Spindle cell squamous carcinoma
 - Basaloid squamous cell carcinoma
 - Adenosquamous carcinoma
 - Others
- For a detailed discussion of these histologic variants, see Section 5, Larynx.
- Carcinoma cuniculatum
 - Represents cutaneous equivalent of verrucous carcinoma
 - Term cuniculatum derived from the Latin *cuniculus*, meaning rabbit burrow, so named for the numerous crypts and sinuses on the tumor mass resembling rabbit burrows
 - Primarily occurs on the soles of the feet
 - May rarely occur on the skin of the face and/or in oral cavity
 - Slow but persistent growth and capacity to erode soft tissue structures, including bone
 - Surgical resection is the preferred treatment.
 - Generally behave indolently and do not metastasize but may recur.

MALIGNANT (MINOR) SALIVARY GLAND TUMORS OF THE ORAL CAVITY

- For more detailed discussion see Section 7, Salivary Glands.
- Up to approximately 25% of all salivary gland tumors occur in the oral cavity.
- May occur anywhere in the oral cavity but among the most common sites include:
 - Palate, buccal mucosa, lips
- Large percentage of intraoral minor salivary gland tumors are malignant:
 - Reported to be up to approximately 50%
- All subtypes of malignant salivary gland tumors may occur in minor salivary gland sites, but the most common types include:

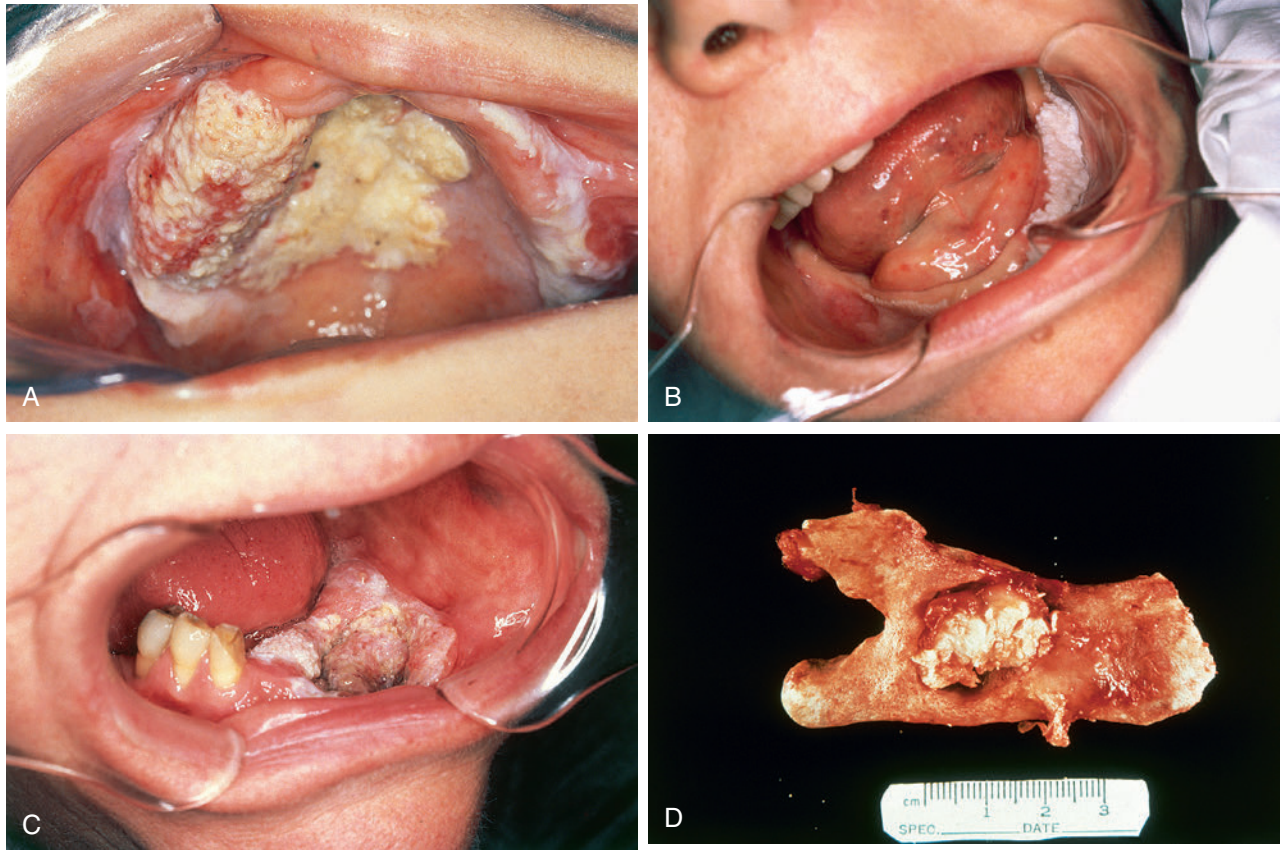

Fig. 6-55. Clinical and gross appearance of oral verrucous carcinoma.

Verrucous carcinoma of various sites of the oral cavity, including one that invaded bone. See Section 5, Larynx, for histologic images of verrucous carcinoma.

- Mucoepidermoid carcinoma
- Adenoid cystic carcinoma
- Polymorphous low-grade adenocarcinoma
- Some of more common malignant major salivary gland tumors are uncommon in minor salivary gland locations, including acinic cell carcinoma:
 - In the presence of a salivary gland neoplasm suggesting a diagnosis of an acinic cell carcinoma, consideration for alternative diagnoses including but not limited to mammary analogue secretory carcinoma (MASC) should be considered; see Section 7, Salivary Glands.
- Select malignant salivary gland carcinomas, including polymorphous low-grade adenocarcinoma and clear cell carcinoma, predilect to minor salivary glands, in particular to the oral cavity.
- All minor salivary gland tumors are unencapsulated; as such, the differentiation of a benign tumor from a malignant tumor is often predicated on the presence or absence of invasion, the latter including:
 - Into adjacent minor salivary gland parenchyma
 - Into fibroconnective tissues (e.g., fat, skeletal muscle)
 - Peri- and intraneural invasion (i.e., neurotropism)
 - Lymph-vascular space invasion
 - Extension to and/or into the surface epithelium is not diagnostic of invasion or malignancy.
 - Metastatic disease is essentially diagnostic of a malignant neoplasm.

Cribriform Adenocarcinoma of Minor Salivary Glands

Definition: Distinct low-grade minor salivary gland neoplasm occurring mostly, but not exclusively, in the base of the tongue that histopathologically resembles papillary thyroid carcinoma with frequent metastases at the time of presentation but overall indolent behavior.

- For a more complete discussion see Section 6, Salivary Glands.

NONEPITHELIAL MALIGNANT NEOPLASMS

Mucosal Malignant Melanoma

Definition: Neural crest–derived neoplasms originating from melanocytes and demonstrating melanocytic differentiation.

- For a more complete discussion see Section 1, Sinonasal Tract.
- Approximately 15% to 25% of all malignant melanomas arise in head and neck sites.
- Of the head and neck malignant melanomas more than 80% are of cutaneous origin.
- Mucosal malignant melanomas of the upper aerodigestive tract represent from 0.5% to 3% of malignant melanomas of all sites:
 - Of noncutaneous head and neck malignant melanomas, majority are of ocular origin
 - Most common site of the upper aerodigestive tract is oral cavity followed by the sinonasal tract
 - Approximately 6% to 8% originate in the mucous membranes of the upper aerodigestive tract.

Oral Cavity Mucosal Malignant Melanoma

- No gender predilection; wide age range but most often occurs in the fourth to seventh decades of life; rarely occurs in pediatric ages
- May occur in any site of the oral cavity:
 - Most common sites of occurrence in the oral cavity include palate, maxillary alveolus, and gingivae
 - Less common sites of occurrence include buccal mucosa, floor of mouth, tongue, and lips.
- Presentation includes presence of a pigmented, painless mass:
 - Rapid enlargement of the lesion may be associated with pain.
 - Surface ulceration may be identified in up to one third of cases.
- No known cause
- Macroscopic, microscopic, histochemical, immunohistochemical, and ultrastructural features are similar to those of melanomas of other sites (see Section 1, Sinonasal Tract):
 - Junctional activity and/or in situ melanoma can be identified but is not required for diagnosis.
 - Although uncommon, desmoplastic subtype may also occur in mucosal sites, including the oral cavity.
- Molecular genetics:
 - Molecular findings of primary mucosal malignant melanomas vary from those of malignant melanomas of sun-exposed (i.e., cutaneous) sites.
 - Mutations in *BRAF* gene:
 - Uncommon in mucosal malignant melanomas
 - Present in 50% to 60% of cutaneous melanomas
 - Suggest that ultraviolet exposure plays a role in genesis of *BRAF* mutations in cutaneous melanoma
 - Subset of mucosal malignant melanomas harbor somatic mutations in c-kit gene in <20%:
 - Strong immunoreactivity for CD117 associated with oncogenic mutations
 - May have clinical implications because tyrosine kinase inhibitor–targeted therapy may be effective for c-kit–mutated tumors
- Similar to other mucosal malignant melanomas, possibility of metastasis to the oral cavity from a separate melanoma must be considered prior to rendering the diagnosis of a primary oral mucosal malignant melanoma:
 - Cutaneous melanomas may metastasize years to decades after initial diagnosis, so detailed clinical history to include prior diagnosis of a cutaneous melanocytic lesion is indicated.
 - Histologic review, if possible, of any previously excised melanocytic lesion is highly desirable.
- Melanin pigmentation of oral cavity can also be seen in association with exogenous and endogenous pigmentation, which may clinically raise concern for a diagnosis of malignant melanoma:
 - Amalgam tattoo (Fig. 6-56)
 - Exogenous pigmentation of oral cavity includes foreign body material and oral tattoo most commonly associated with amalgam, although any implanted, pigmented material may result in “tattoo” such as graphite (from pencils), coal, metal, and plant material.
 - Amalgam or other metal tattoo may be observed on radiograph if the metal fragments are of sufficient density.
 - Macules appear black, blue, or gray, and borders may be well defined or diffuse; borders may change over time and may be asymmetric, potentially raising clinical concern for a melanoma.
 - Any mucosal surface may be affected by tattoo:
 - Palate is more often involved in pencil implant
 - Histologically, foreign material identified in submucosa appearing as scattered solid fragments of fine black or dark-brown granules surrounded by a mild chronic inflammatory cell infiltrate, although marked chronic inflammation and granulomatous response may be identified.
 - Biopsy to exclude melanoma is generally adequate therapy for a pigmented macule.

Fig. 6-56. Amalgam tattoo.

Foreign material is present within the submucosa appearing as scattered fine black or dark-brown granules surrounded by a mild chronic inflammatory cell infiltrate.

- Endogenous pigmentation of oral cavity includes byproducts of red blood cells or melanocytes and includes melanotic macule and black hairy tongue.
 - Melanotic macule:
 - Mucosal lesion similar to a freckle or ephelis of the skin, but association with sun exposure is less clear as the lesion may occur on the lips or the intraoral mucosa
 - May occur at any age but is more common in adulthood
 - Appears as a solitary, small, tan to brown, homogeneous, symmetric, nonpalpable pigmentation of the oral mucosa
 - Labial melanotic macule has been found to be more common in the lower lip of adult women.

- Increased melanin without atypia or pleomorphism in the basal layer of the mucosa is the hallmark of melanotic macule:
 - Melanocytes are seen as individual cells that do not show a tendency to nest and/or migrate throughout the surface epithelium.
 - Absence of nuclear atypia and mitotic activity
 - Melanin is accumulated in the cell body of the keratinocytes and is scarce in the dendritic cells of the upper layers of the epithelium.
 - Melanin accumulation may be more prominent at the tips of the rete ridges.
 - Melanin incontinence and melanophage activity may be a finding in the lamina propria.
 - Fontana stain and melanin bleach support the pigment identification as melanin.
- Black hairy tongue
 - Reactive condition resulting in an exaggerated form of filiform papillae on the dorsal surface of the tongue
 - Common condition, particularly found in smokers
 - Dorsal tongue most commonly affected and may be stained yellow, brown, or black
 - Elongation of the filiform papillae results in the hairy appearance, which may range from a coating to a shaggy, matted manifestation
 - Often asymptomatic, but patients may be concerned about the appearance of their tongue.
 - Generally diagnosed clinically but occasionally may be biopsied for confirmation
 - Exact cause is unknown, but black hairy tongue has been associated with a number of predisposing factors, including smoking, medications (e.g., antibiotics), microorganisms (e.g., bacteria, fungi), chemical irritants, and poor oral hygiene; there is no association with Epstein-Barr virus.
 - Histologically, includes hyperkeratosis of the filiform papillae arranged into tall orthokeratin spires is the hallmark of hairy tongue; superficial colonies of bacteria and fungal elements, easily seen in cytologic scraping, admixed with benign squamous cells
 - Improved oral hygiene, tongue brushing, and reduced tobacco use diminish black hairy tongue.
- Treatment for oral mucosal malignant melanoma includes:

- Radical surgical resection
- Lymph node dissection is usually indicated based on the fact that a majority of oral cavity melanomas are advanced at presentation, including reported nodal metastatic rate of up to 75% of cases.
- Adjunctive radiation and chemotherapy of questionable utility but may be given for palliation
- High rate of local recurrence ranging from 31% to 85%
- High rate of distant metastasis:
 - As high as 50% of cases
 - Most frequently to lungs and liver
- Prognosis is poor:
 - 5-year survival rates range from 15% to 25%.
 - Death often occurs within 2 years of diagnosis.
- Unlike cutaneous melanomas, depth of invasion (i.e., Clark levels and Breslow thickness) is not applicable for mucosal malignant melanomas, including those of the oral cavity:
 - Most oral cavity mucosal malignant melanomas are deeply invasive at presentation (i.e., greater than 4 mm).

Neuroendocrine Carcinomas

- Neuroendocrine carcinomas (NEC) represent a heterogeneous group of malignant neoplasms with divergent differentiation along epithelial and neuroendocrine cell lines.
- Uncommon tumor type in the oral cavity.
- See Section 3, Pharynx, and Section 5, Larynx, for a more detailed discussion.

Hematolymphoid Malignant Neoplasms

General Considerations

- Classification schemes have varied over the past few decades to include the Rappaport Classification (1966), National Cancer Institute Working Formulation (1982), Lukes-Collins Revised Classification (1992), and Revised European-American Lymphoma (REAL) Classification (1994); currently, the WHO Classification (2007) is a modification of the REAL Classification.
- Fourth edition of the WHO Classification stratifies neoplasms primarily according to lineage to include:
 - Myeloid
 - Lymphoid
 - Histiocytic/dendritic
- In addition, fourth edition of the WHO Classification incorporates new information, including:
 - New defining criteria for some diseases
 - New entities defined by genetic criteria or by their morphology, immunophenotype, and clinical features
- Lymphomas are subdivided into non-Hodgkin lymphomas (NHL) and Hodgkin lymphoma:
 - In the head and neck, NHL are more common.
- The vast array of clinical and pathologic features of the malignant lymphoproliferative diseases is beyond the scope of this text; the approach here is to describe the more common types of malignant lymphomas affecting the extranodal lymphoid sites of the head and neck primarily of the oral cavity; other site-specific malignant lymphomas are discussed in those specific sections to include:
 - Nasal-type NK/T lymphoma in Section 1
 - Waldeyer ring malignant lymphomas in Section 3
 - Salivary gland malignant lymphomas in Section 6
 - Thyroid gland malignant lymphomas in Section 8

Oral Cavity Hematolymphoid Malignancies

- Hematolymphoid neoplasms of oral mucosal sites are uncommon and include non-Hodgkin lymphomas (NHL) and plasma cell neoplasms:
 - Represent approximately 2% of all extranodal lymphomas
- No gender predilection; may occur at any age but most common in older individuals with median in sixth to seventh decades
- Sites of involvement include palate, gingiva, tongue, buccal mucosa, floor of mouth, and lip:
 - May also include primary intraosseous lymphomas with extension into oral cavity
- Symptoms may include:
 - Discrete mass, mucosal ulceration, paresthesias, pain, and loosening of teeth
 - Lymphomas of the oral cavity include immunocompetent and immunodeficient patients:
- Immunodeficiency-associated lymphomas occur in HIV-positive and post-transplantation patients:
 - HIV-associated oral cavity lymphoma:
 - Almost all occur in men at younger ages than with approximate median age of 40 years
 - Most often are diffuse large B-cell lymphomas (DLBCL)
 - Are EBV positive in a majority of cases (60% to 75%)
 - May also include subtype of DLBCL referred to as plasmablastic lymphoma (Fig. 6-57):
 - Represents a diffuse proliferation of large neoplastic cells, most with morphology of immunoblasts but with immunophenotype of plasma cells

Fig. 6-57. Plasmablastic lymphoma of the oral cavity.

A, Diffuse cellular infiltrate with interspersed macrophages can be seen that on low power create a starry sky appearance. **B**, Neoplastic cells are large with eccentric vesicular-appearing nuclei, prominent nucleoli, and basophilic cytoplasm. Lesional cells are immunoreactive for **(C)** melanoma-associated antigen (MUM1) (nuclear staining) and **(D)** CD138. **E**, In situ hybridization for Epstein-Barr–encoded RNA (EBER) is positive (nuclear staining). In situ hybridization shows **(F)** lambda light chain positive and **(G)** kappa light chain negative.

Continued

Fig. 6-57, cont'd

- Occurs primarily in HIV-positive individuals but also identified in iatrogenically immunosuppressed patients, HIV-negative, immunocompetent individuals (mostly older adults); rare in children
- Rapidly growing tumors localized to oral cavity and jaw
- Histology:
 - Neoplastic cells show plasmablastic morphology characterized by large cells with eccentric vesicular-appearing nuclei, central prominent nucleoli, paranuclear hof, and basophilic cytoplasm.
 - Generally there is an absence of maturation to plasma cells, although some cases may show maturation toward plasma cells.
 - Frequent single cell or zonal necrosis
 - Starry sky appearance (diffuse growth interspersed by macrophages)
 - High mitotic rate activity
- Immunohistochemistry:
 - Typically express markers associated with post-germinal center stage of differentiation or with plasma cells, including melanoma-associated antigen (MUM1) expression (nuclear staining)
 - CD38, CD138, VS38
 - >50% express monotypic cytoplasmic immunoglobulin (kappa < lambda)
 - Subset are CD79a positive
 - Usually negative for CD45, CD20, and PAX5
 - High proliferative index (60% to 90%)
 - EBV positive (in situ hybridization for Epstein-Barr encoded RNA [EBER]) in approximately 75% of cases

- No association with human herpesvirus-8 (HHV-8, Kaposi sarcoma-associated herpesvirus)
- Molecular genetics:
 - Translocation between *MYC* and *IGH* [t(8;14)] reported but prevalence is uncertain
- Other oral cavity HIV-associated lymphomas:
 - Almost all are diffuse high-grade lymphomas.
 - Most are diffuse large B-cell lymphomas.
 - Occasional cases include peripheral T-cell lymphoma, Burkitt lymphoma, and anaplastic large cell lymphoma of T-lineage.
 - Most contain EBV whether of B-cell or T-cell lineage.
- Oral cavity lymphomas in immunocompetent individuals
 - Wider variety of high-grade and low-grade types than in immunodeficient individuals
 - Almost all are B-cell lymphomas
 - Majority are EBER negative (9% to 19% may be EBER positive):
 - Diffuse large B-cell lymphomas (50%) > follicular lymphoma > marginal zone lymphoma >> others:
 - Follicular lymphomas predilect to palate
 - Marginal zone lymphomas arise in minor salivary glands
- Treatment and prognosis:
 - Staging reveals localized disease in approximately 70% of cases.
 - Outcome depends on:
 - Stage, type of lymphoma, patient's HIV status
 - Excellent prognosis seen in patients with localized, histologically low-grade lymphomas
 - Significantly worse prognosis in patients with disseminated, high-grade lymphomas
 - Patients with HIV/AIDS, including those with plasmablastic lymphoma, have poor prognosis.

Extramedullary Plasmacytoma

- Uncommon but may occur in the oral cavity
- See Section 4, Pharynx, for a more complete discussion.

SARCOMAS OF THE ORAL CAVITY

- In general, sarcomas of the oral cavity are uncommon.

- Although uncommon, virtually all types of sarcomas may occur in these sites.

Rhabdomyosarcoma (RMS)

Definition: Malignant neoplasm showing skeletal muscle differentiation.

- For more complete discussion see Section 3, Pharynx.

Leiomyosarcoma (LMS)

Definition: Malignant neoplasm with smooth muscle differentiation.

- LMS is covered in greater detail in Section 1, Sinonasal Tract.

Liposarcoma

Definition: Malignant neoplasm with adipocyte cell differentiation.

- For more complete discussion see Section 5, Larynx and Trachea.

Malignant Peripheral Nerve Sheath Tumors (MPNST)

Definition: Malignant tumor of peripheral nerves or having differentiation along the lines of various elements of the nerve sheath.

- For more complete discussion see Section 4, Neck.

Undifferentiated Pleomorphic Sarcoma

Definition: High-grade, pleomorphic malignant neoplasm without specific differentiation and not associated with differentiated sarcoma:

- For more complete discussion see Section 1, Sinonasal Tract.

Fibrosarcoma

Definition: Malignant tumor of fibroblasts and myofibroblasts lacking evidence of other types of cellular differentiation.

- For more complete discussion see Section 1, Sinonasal Tract.

Alveolar Soft Part Sarcoma (ASPS) (Fig. 6-58)

Definition: Rare clinically and morphologically distinct, slow-growing but highly malignant soft tissue sarcoma of uncertain histogenesis.

Clinical

- Represents less than 1% of all sarcomas
- More common in women than men prior to age 30; slightly more common in men than women after age 30
- Occurs at any age but is most frequent in the second through fourth decades of life:
 - Rarely occurs prior to 5 years of age
- Most common sites of occurrence is age dependent:
 - In adults, most often occurs in the lower extremities, especially the anterior upper thigh, as well as the buttock
 - In infants and children, most often occurs in the head and neck, in particular the tongue and orbit
 - Isolated cases occur in a wide variety of other sites, including chest wall, trunk, upper extremities, mediastinum, lung, female genital tract, retroperitoneum, stomach, and bone.
- Presentation is usually as a slow-growing, painless mass:
 - Due to slow growth and lack of pain, these lesions may be clinically overlooked and initial presentation may be that of metastatic disease:
 - Early metastasis is a characteristic clinical feature.
 - Common metastatic sites include the brain and lungs:
 - As a result of metastatic disease, especially to the brain, initial complaints may include headache and visual disturbances.
 - Orbital involvement may be associated with proptosis and lid swelling.
- As a result of its rich vascularity, some lesions may be associated with:
 - Pulsation with an audible bruit
 - Massive hemorrhage during surgery
- Radiology:
 - Angiography and contrast-enhanced CT scans: hypervascularity and prominent draining veins
 - MRI: high signal intensity on T1- and T2-weighted images
- No known cause

Pathology

Gross

- Poorly delineated or circumscribed, soft to friable lesions appearing pale gray to yellow; necrosis and hemorrhage may be evident, especially in larger tumors

Histology

- Characterized by an alveolar, organoid, or nestlike growth separated by thin-walled fibrovascular septae lined by a single layer of flattened endothelial cells:

Fig. 6-58. Alveolar soft part sarcoma of the tongue.

A, Characteristic alveolar growth separated by thin-walled fibrovascular septae. **B,** Neoplastic cells are large, round to polygonal in shape with vesicular nuclei, eosinophilic nucleoli, and abundant granular, eosinophilic cytoplasm. **C,** More solid to diffuse growth pattern with less conspicuous or even absent alveolar or nest-like growth may occur in infants and children. **D,** Characteristic diastase-resistant, PAS-positive intracytoplasmic crystalline-like material (*arrows*). **E,** Intracytoplasmic MyoD1 immunoreactivity. **F,** TFE3 (nuclear) staining.

- Loss of cohesion due to necrosis and/or central degeneration within the cell nests results in pseudoalveolar pattern of growth.
- In younger ages (i.e., infants and children) there is a greater tendency to more solid/diffuse pattern of growth, in which the nestlike pattern is inconspicuous or absent.
- Neoplastic cells are large and round to polygonal in shape with little variation in size and shape characterized by:
 - Large, vesicular nuclei with one or more nucleoli
 - Abundant granular, eosinophilic to occasionally clear/vacuolated cytoplasm with distinct cell borders
 - Concave “apple bite” contour to nuclei may be seen especially relative to lingual-based tumors
 - Intramuscular localization for lingual tumors
 - Scarce mitotic activity; nuclear atypia, and multinucleation may infrequently be present.
 - Superficial ulceration may be identified in mucosal-based (e.g., lingual) lesions.
 - Necrosis, cystic change, hemorrhage, and myxoid change may infrequently be identified.
- Prominent dilated veins can be found along the periphery of the tumor.
- Lymph-vascular invasion is a frequent and readily identifiable finding, explaining the tendency to early metastasis associated with this tumor; perineural invasion may be identified.
- Histochemistry:
 - Intracytoplasmic diastase-resistant, PAS-positive rhomboid, or rod-shaped crystalline material considered to be a diagnostic feature for this tumor:
 - Seen in approximately 80% of tumors
 - Can be identified in primary and metastatic lesions
 - Variably identified from case to case:
 - In some tumors crystals are abundantly present and readily identified whereas in other tumors may be rare to absent.
 - Intracytoplasmic diastase-resistant, PAS-positive granules are present, believed to represent precursors of the crystals
 - Nature of crystals not been entirely determined but expression of a monoclonal antibody to monocarboxylate transporter 1 (MCT1) identified in cytoplasm of cells:
 - MCT1 belongs to family of transporter proteins that catalyzes rapid transport of monocarboxylates across plasma membranes.
 - Protein normally associated with rough endoplasmic reticulum and is transported to plasma membrane in association with its chaperone CD147
 - MCT1 and CD147 identified in surface of cells of ASPS as well as in cytoplasm in region of crystals
- Immunohistochemistry:
 - Neoplastic cells:
 - Variable reactivity for vimentin and myogenic markers, including desmin, muscle-specific actin, and MyoD1:
 - MyoD1 reactivity is cytoplasmic, not nuclear.
 - Initially expression of *MyoD1*, a regulatory gene in the control of myogenic differentiation, strongly supported skeletal muscle differentiation for ASPS, but the inability to consistently duplicate this finding, as well as the absence of convincing evidence of skeletal muscle differentiation utilizing more sophisticated techniques, raises doubts relative to skeletal muscle differentiation.
 - Myogenin (Myf-4), myoglobin negative
 - TFE3 immunoreactivity (nuclear staining) present in most but not all cases:
 - Can be identified in other neoplasms including paraganglioma, granular cell tumor, adrenal cortical carcinoma, renal Xp11 translocation carcinoma
 - S100 protein and neuron-specific enolase may be identified in approximately 25% of cases but considered nonspecific reactivity.
 - Negative for cytokeratins, epithelial membrane antigen, neurofilament protein, GFAP, chromogranin, synaptophysin, HMB45, and CD68 (KP-1), and inhibin
 - Intracytoplasmic granules:
 - Immunoreactive for MCT (a monocarboxylate transporter) and CD147 (chaperone protein for MCT)
- Electron microscopy:
 - Characteristic feature is the presence of membrane-bound or free rhomboid to rod-shaped crystals arranged in parallel with a periodicity of 10 nm
 - Cytoplasm contains numerous mitochondria, prominent rough endoplasmic reticulum, well-developed Golgi complexes, and glycogen.
 - Tumor cells are surrounded by discontinuous basal lamina.
 - Rare junctional complexes (desmosomes and hemidesmosomes) are identified.
- Cytogenetics and molecular genetics:
 - Specific translocation der(17)t(x;17)(p11;q25)
 - Unbalanced translocation results in fusion of the TFE3 transcription factor gene on Xp11.2 (a member of the basic-helix-loop-helix family of transcription factors) to *ASPCR1* gene (referred to as ASPL) at 17q25

- *ASPCR1/TFE3* fusion gene:
 - Encodes for a fusion gene that localizes to nucleus
 - Functions as aberrant transcription factor
 - Among soft tissue sarcomas considered highly specific and sensitive for ASPS
 - Also found in association with subset of pediatric renal cell carcinoma characterized by:
 - Pseudopapillary architecture, epithelioid cells with abundant clear cytoplasm and well-defined borders, and psammomatous calcifications
 - These tumors have been termed Xp11 translocation carcinoma.

Differential Diagnosis

- Rhabdomyoma
- Paraganglioma
- Granular cell tumor
- Metastatic renal cell carcinoma
- Alveolar rhabdomyosarcoma
- Crystal storing histiocytosis
- Metastatic ASPS from soft tissue site (e.g., thigh) to the oral cavity:
 - Rare but reported occurrence

Treatment and Prognosis

- Complete surgical resection is the preferred treatment:
 - Surgery includes radical excision of the primary and any metastatic foci.
- Adjunctive radiation and/or chemotherapy have been advocated predicated on several factors:
 - Resectability of the tumor
 - Presence of metastatic disease
- Local recurrence is uncommon.
- Metastatic disease is a frequent occurrence:
 - Can be seen early in the disease course
 - May be the initial presentation
 - Frequently occurs to brain, lungs, and bone
 - Nodal metastasis is uncommon.
- Prognosis is poor:
 - 60% 5-year survival
 - 38% 10-year survival
 - 15% 20-year survival
- Prognostic findings include:
 - Age at diagnosis:
 - Improved prognosis associated with younger age:
 - Less tendency to metastasize
 - Tend to be smaller tumors
 - More amenable to complete resection
 - Localization to the tongue and orbit may allow for earlier diagnosis and smaller tumor size.

- Tumor size:
 - Larger tumors often associated with distant metastasis
- Presence of metastasis:
 - Portends poor prognosis but resection of solitary metastasis may be of prognostic benefit
- Location of tumor:
 - Lingual alveolar soft part sarcoma reported to have a substantially better prognosis than alveolar soft part sarcomas of other sites

Angiosarcoma

Definition: Malignant neoplasm with endothelial cell differentiation.

- For more complete discussion see Section 1, Sinonasal Tract.

Kaposi Sarcoma (KS)

(Figs. 6-59 and 6-60)

Definition: Locally aggressive endothelial tumor uniformly associated with human herpesvirus-8 (HHV-8) infection.

Synonym: Angiosarcoma complex

Clinical

- Occurs in four clinical forms:
 - Classic indolent or chronic KS
 - AIDS-related KS
 - Iatrogenic (transplantation-associated) KS
 - Endemic (African) KS
- Cause:
 - Human herpesvirus-8 (HHV-8) is etiologic agent:
 - Large enveloped double-stranded DNA virus
 - Represents eighth human herpesvirus, hence the designation as human herpesvirus-8 (HHV-8)
 - Also known as Kaposi sarcoma–associated herpesvirus (KSHV)
 - HHV-8 infects endothelial cells as well as peripheral blood monocytes and B lymphocytes in patients with KS.
 - Transmission occurs primarily through saliva.
 - Found in all forms of KS

“Classic” Indolent or Chronic KS

- Considered rare
- More common in men (90%) than women; most common in the sixth through eighth decades of life
- Most common in people of Eastern European and/or Mediterranean descent, as well as in equatorial region of Africa

Fig. 6-59. Kaposi sarcoma of various head and neck sites.

A, Multiple, discrete, oval, raised, blue-red, or violaceous cutaneous papules or nodules. **B**, Raised, reddish-appearing nodule located immediately outside to the external auditory canal. **C**, Well-delineated and raised palatal mass with a bright red appearance. **D**, Ill-defined deep-red tonsillar polypoid mass. **E**, Circumscribed, raised, red parotid lesion.

Fig. 6-60. Kaposi sarcoma.

A, Spindle cell proliferation with fascicular growth and presence of slit-like spaces containing erythrocytes that extravasate into the spindle cell component. **B**, Spindle cells are elongated with scant cytoplasm and indistinct cell borders; separating the spindle cell proliferation are slit-like spaces containing erythrocytes. **C**, Hyaline globules (*arrows*) are a characteristic but not specific finding. **D**, Scattered mitotic figures can be found (*arrow*). Lesional cells are immunoreactive for **(E)** CD31, **(F)** CD34, and **(G)** latency-associated nuclear antigen (LANA-1).

Fig. 6-60, cont'd

- Predominantly a cutaneous-related tumor occurring on extremities, with the lower extremity more common than the upper extremity:
 - Visceral and lymph node involvement is unusual in the absence of cutaneous disease.
 - Initial presentation in the head and neck is decidedly uncommon; with progression of disease from more usual locations, mucosal sites in the head and neck can be affected, including:
 - Oral cavity (palate, tongue, gums, lips, buccal mucosa), tonsils, pharynx, and larynx
- Cutaneous lesions characterized by the presence of purplish-reddish to blue-appearing plaques or nodules with or without ulceration; lymphedema of the involved extremity may also be present.
- Association with a second malignant neoplasm (leukemia, lymphoma, myeloma) or autoimmune disease (autoimmune hemolytic anemia)
- Not associated with the human immunodeficiency virus (HIV) or with the development of AIDS

AIDS-Related KS

- Most aggressive form
- Found in HIV-infected individuals and/or AIDS patients; occurs in approximately 10% of all patients with AIDS
- May be seen in all AIDS-related risk groups but appears to be more common among male homosexuals; occurs at a much younger age as compared with the classic form, most frequently occurring in the fourth decade of life
- Cutaneous lesions most common on the face, lower extremities, and genitals:
 - Visceral and lymph node involvement may occur in the absence of cutaneous disease:
 - Oral mucosa, lymph nodes, gastrointestinal tract, and lungs frequently involved

- Mucosal lesions may be seen throughout the upper aerodigestive tract with the oral cavity and pharynx (oropharynx and hypopharynx) among the more common sites of occurrence:
 - Intraoral sites include palate, gingiva, tongue, buccal mucosa, other
 - Salivary glands (i.e., parotid gland) may be involved.
 - Sinonasal, nasopharyngeal, and laryngeal involvement is uncommon.
- Mucocutaneous lesions vary and include:
 - Early lesions:
 - Solitary or multiple bright red to blue-appearing lesion(s)
 - Later lesions:
 - Purplish-reddish to violaceous mucosal plaque, papule, or nodule with or without ulceration
 - Multiple mucocutaneous lesions are commonly seen.
 - Generalized lymphadenopathy and visceral involvement also frequently occur:
 - Visceral involvement may be clinically silent or may be symptomatic, depending on location of lesion(s) and extent of involvement.
- Identification of KS often is the initial manifestation of AIDS leading to its diagnosis.

Iatrogenic (Transplantation-Associated) KS

- Occurs in solid organ transplant recipients (e.g., renal transplantation) and in patients receiving immunosuppressive therapy
- In this setting, KS may develop months to years after transplantation or immunosuppressive therapy.
- May occur at any age
- May occur in cutaneous or visceral sites:
 - Predilection to skin of the lower extremities
 - Visceral involvement frequently occurs.
- Appearance similar to that of other forms of KS

Endemic (African) KS

- Not associated with HIV infection or AIDS
- More common in males than females; occurs in children and middle-aged adults in equatorial Africa
- Present with localized or generalized lymphadenopathy, including cervical, inguinal, or hilar lymph node chains:
 - Lymph node involvement frequently occurs in children.
- May be localized to cutaneous sites of the extremities:
 - Visceral involvement is fairly common in adults.
- Appearance similar to that of other forms of KS
- Clinical course is variable:
 - In adults typically indolent although may be protracted

- In children may be aggressive:
 - Lymphadenopathic form is rapidly progressive and highly lethal.

Pathology

Gross

- Early lesions in the AIDS group appear as flat, red to pink areas and tend to be small.
- More advanced AIDS-related and “classic” type of Kaposi sarcoma appear as raised, blue-red, or violaceous papules or nodules of varying sizes that with time may coalesce to form plaques.

Histology

NOTE: Regardless of the clinical setting, the histology of the more advanced lesions is essentially the same.

- Differs according to stage of the disease:
 - Early (patch) stage:
 - Slight increase in vascular spaces
 - More advanced (nodular) stage:
 - Unencapsulated and infiltrative composed of spindle cells in a fascicular growth
 - Spindle cells are elongated and rather uniform with scant cytoplasm and indistinct cell borders.
 - Scattered mitotic figures can be identified.
 - Separating the spindle cell proliferation are slit-like spaces containing erythrocytes that commonly extravasate into the spindle cell component.
 - Characteristic but not specific feature is presence of hyaline globules:
 - Intracellular and extracellular
 - Diastase-resistant, PAS-positive
- Typically there is an absence of nuclear pleomorphism and increased mitotic activity:
 - Aggressive forms of KS may include marked nuclear pleomorphism and increased mitotic activity.
 - May occur from beginning (ab initio)
 - May occur as transitional from areas of limited nuclear pleomorphism and increased mitotic activity
- Lymph node involvement may include multiple tumor foci located in capsular and sinusoid regions:
 - Early lesions may appear as foci of mild angiectasia and vascular proliferation in subcapsular sinuses.
- Histochemistry:
 - Intracellular and extracellular hyaline globules are diastase resistant, PAS positive.
- Immunohistochemistry:
 - Latency-associated nuclear antigen (LANA-1) is KSHV latent protein:
 - LANA expressed during latent HHV-8 infection:

- Expression (nuclear staining) by immunohistochemical staining found in all cases of KS
- More than 90% of cases show strong nuclear staining.
- Present in infected cells (both endothelium and spindle-shaped cells)
- Expression not reported in non-KS neoplasms except for primary effusion lymphoma and Castleman disease
- Very useful in early lesions with subtle histologic features
- Additional immunohistochemical findings include:
 - CD31, CD34, and ERG:
 - Both endothelium and spindle-shaped cells:
 - Typically negative for factor VIII-related antigen
 - Vascular endothelial growth factor 3 (VEGFR-3) and podoplanin (D2-40) positive (membranous and cytoplasmic)
- Electron microscopy:
 - Presence of hexagonal nucleocapsids and mature enveloped virions typical for herpesvirus may be found
 - Two abnormalities of the rough-surfaced endoplasmic reticulum may be identified in KS cells including tubuloreticular structures (TRS) and intracisternal paracrystalline inclusions (IPI):
 - 2 types of TRS are distinguished: loose TRS (LTRS) and compact TRS (CTRS)
 - LTRS is observed in endothelial cells from all types of KS.
 - CTRS confined to AIDS-associated KS
 - CTRS, but not LTRS, may represent an ultrastructural marker for AIDS-associated KS.
- Cytogenetics and molecular genetics:
 - No relevant genetic changes reported

Differential Diagnosis

- Lobular capillary hemangioma
- Angiosarcoma
- Spindle cell hemangioma/hemangioendothelioma:
 - Presence of cavernous blood vessels and epithelioid endothelial cells allow for differentiation from KS.
- Kaposiform hemangioendothelioma ([Fig. 6-61](#)):
 - Rare, locally aggressive vascular neoplasm often associated with consumptive coagulopathy and thrombocytopenia (Kasabach-Merritt syndrome) and characterized by a Kaposi sarcoma-like fascicular spindle cell growth
 - Typically occurs in infants and children in the first decade of life:
 - Rare in adults

Fig. 6-61. Kaposiform hemangioendothelioma of the palate.

A, Irregular tumor nodules within soft tissue. **B**, Spindle cell areas merge with glomeruloid nests of epithelioid-appearing cells. **C**, Capillary-like areas as well as slit-like vascular lumina containing erythrocytes resemble Kaposi sarcoma. **D**, Intravascular fibrin thrombi can be seen. **E**, High magnification of areas resembling Kaposi sarcoma; immunoreactivity for **(F)** D2-40 (podoplanin) and **(G)** CD31.

Continued

Fig. 6-61, cont'd

- Common site of occurrence includes soft tissue of extremity; less common sites include retroperitoneum, mucosal sites of head and neck, mediastinum
- No known association with HHV-8 or any other viruses
- Histology includes:
 - Lobular architecture separated by fibrous septa
 - Presence of a spindle cell proliferation in a fascicular growth interspersed with numerous capillaries
 - Fascicles may be tightly packed or loosely arranged, containing slit-like or sieve-like vascular lumina.
 - Fibrin thrombi can be found in slit-like spaces and capillaries.
 - “Glomeruloid” bodies may uncommonly be identified.
 - Immunohistochemistry (spindle cells):
 - Slit-like KS-like vascularity reactive for lymphatic markers (PROX1, D2-40 [podoplanin], VEGFR-3)
 - Spindle cell reactive for CD31 and CD34
 - No expression of HHV-8
 - Negative for GLUT-1, a marker found in association with infantile hemangioma
 - Mucosal lesions are treated by surgical resection.
 - Prognosis varies per site and size of the tumor:
 - Large intraabdominal lesions associated with consumptive coagulopathy, has a poor prognosis
 - Mucosal-based lesions associated with more favorable outcome and rarely recur after resection

- Spindle cell squamous carcinoma
- Fibrosarcoma

Treatment and Prognosis

- Other than for diagnostic purposes, surgery is generally not used in treatment.
- Radiation and/or chemotherapy are the preferred treatments:
 - Chemotherapeutic management used in AIDS patients, including azidothymidine (AZT), vincristine, and vinblastine
- Classic indolent form is associated with a prolonged clinical course and low mortality rates:
 - 10% to 20% disease-related mortality
- AIDS-related KS:
 - Prior to advent of highly active anti-retroviral therapy (HAART) had much more aggressive disease course, with increased mortality rates (90%) as a result of the constellation of problems in this group including opportunistic infections and visceral KS
 - Advent of HAART resulted in:
 - Prevention in the development of KS
 - Substantial disease regression
 - Current treatments for AIDS-related KS include ART and chemotherapy for patients with advanced symptomatic disease
- Iatrogenic KS:
 - Clinical course is variable:
 - May resolve after cessation of immunosuppressive therapy
 - May behave aggressively with higher mortality rates due to pulmonary and gastrointestinal involvement

MATRIX-FORMING AND RELATED MALIGNANT NEOPLASMS

Osteosarcoma

Definition: Malignant osteoid-producing neoplasm arising from bone.

Synonym: Osteogenic sarcoma

- Osteosarcomas are broadly classified into those occurring primarily in medullary cavity and those predominantly situated on surface of bone.
 - Medullary osteosarcoma:
 - Conventional (see later)
 - Osteosarcoma of jawbones (see later)
 - Postradiation sarcoma
 - Osteosarcoma in Paget disease
 - Osteosarcoma in other benign conditions
 - Telangiectatic osteosarcoma
 - Small cell osteosarcoma

- Low-grade osteosarcoma
- Multicentric osteosarcoma
- Surface (juxtacortical) osteosarcoma:
 - Paraosteal osteosarcoma:
 - Well-differentiated (low-grade) osteosarcoma arising on surface of bone
 - All surface osteosarcomas are rare but paraosteal osteosarcoma is the most common type, representing approximately 65% of all surface osteosarcomas.
 - Cause unknown
 - More common in females than males; affects young adults approximately decade older than conventional osteosarcoma
 - Symptoms include painless swelling, but pain with or without swelling may be present.
 - Most common site of occurrence is femur (posterior cortex of distal femoral metaphysis) followed by the proximal portions of tibia and humerus:
 - Flat bones rarely involved
 - Plain radiographs almost always diagnostic:
 - Appears heavily mineralized mass attached by broad base to underlying cortex
 - Histology includes relatively hypocellular stroma and well-formed bony trabeculae:
 - Spindle cells show minimal cytologic atypia and rare mitotic figures.
 - Bony trabeculae arranged in parallel arrays
 - Invasion of medullary cavity may occur.
 - Cartilaginous differentiation appearing as hypercellular nodules interspersed among bony trabeculae seen in approximately 50% of cases; may form “caps” along periphery of lesion
 - Approximately 15% have foci of high-grade sarcoma (dedifferentiation) at initial presentation or in recurrent tumor.
 - Areas of dedifferentiation may include osteosarcoma, fibrosarcoma, undifferentiated pleomorphic sarcoma (formerly malignant fibrous histiocytoma).
 - Aggressive tumors associated with early metastasis (to lungs) poor prognosis
 - Metastatic disease may include either low-grade, high-grade, or both components.
 - Surgical resection is preferred treatment:
 - Pre- and postoperative chemotherapy not usually indicated
 - Locally aggressive but limited metastatic potential
 - Very good prognosis with 90% long-term survival
 - Periosteal osteosarcoma
 - Predominantly chondroblastic, moderately differentiated osteosarcoma arising on surface of bone without medullary involvement
 - Much less common than parosteal osteosarcoma but more common than high-grade surface osteosarcoma
 - More common in females than males; occur in children and young adults; highest incidence in second decade
 - Symptoms may include pain and/or swelling; a palpable mass may be present.
 - Almost exclusively found in appendicular skeleton, especially the diaphyseal region of tibia and femur
 - Plain radiographs show a lucency in saucer-shape depression in cortex.
 - CT and MRI assist in excluding marrow involvement.
 - Histologic findings include:
 - Lobulated, chondroid-appearing neoplasm
 - Irregular spicules of bone in center of cartilaginous nodules
 - Moderate cytologic atypia is present.
 - Surgical resection is the preferred treatment; preoperative and postoperative chemotherapy not usually indicated
 - Better prognosis than conventional osteosarcoma but may be metastatic in up to 18% of cases
 - High-grade surface osteosarcoma:
 - Malignant bone-forming neoplasm with high-grade cytomorphology arising on surface of bone
 - Least common surface osteosarcoma representing approximately 10% of all cases
 - More common in males than females; occurs in young adults with highest incidence in second to third decades
 - Most common in long tubular bones, including distal femur, proximal humerus, and distal radius:
 - >50% are diaphyseal.
 - Histologically high grade
 - Multimodality therapy including preoperative chemotherapy followed by surgery
 - Very aggressive with poor prognosis:
 - 5-year survival of approximately 46%
- Extraosseous type:
 - Arises in soft tissues and viscera without connection to bone
 - Diagnosis is predicated on:
 - No connection to an osseous site
 - Presence of osteoid in association with a sarcomatous stroma
 - Exclusion of a metastasis to a soft tissue site from a osseous-related osteosarcoma

- May occur de novo or secondary to radiotherapy
- Majority occurs in the lower extremity, especially the thigh.
- Complete surgical resection to include tumor-free margins is the preferred treatment.
- Aggressive tumors with tendency to local recurrence and distant metastasis:
 - Recur within 1 year of diagnosis
 - Metastasize most frequently to the lungs, but may also spread to lymph nodes, bone, liver
 - Up to 20% of patients have metastatic disease at initial presentation.
- In general, for all sites, including the head and neck, the conventional type is the most common; juxtacortical and extraosseous types are uncommon in the head and neck.

General Considerations

- Second to multiple myeloma, osteosarcoma is most common malignant bone tumor, representing approximately 35% of all malignant bone tumors.
- More common in males than females; most common in children, especially in the second decade of life
- Cardinal symptom is pain with or without a palpable mass:
 - Pathologic fracture or detections as incidental finding on imaging uncommon
- Commonly arises in metaphyseal area of long bones of appendicular skeleton, including:
 - Distal femur, proximal tibia, and proximal humerus:
 - Greater than 90% arise in metaphyseal region
 - Less than 10% arise in diaphyseal region
 - Rare in epiphyseal region
- Radiology:
 - Appears as geographic area of destruction in metaphyseal region
 - Poorly demarcated borders/margins
 - Cortex almost always destroyed and tumor extends into soft tissues
 - Periosteum is lifted from underlying cortex giving rise to periosteal new bone formation usually proximal to tumor referred to as Codman's triangle
 - Varying degrees of bone-producing matrix, including calcifying and ossifying osteoid substance seen within the lesion:
 - Matrix has been termed cloud-like
 - Densities may be present in soft tissue extension considered virtually diagnostic.
 - Soft tissue mineralization may be in the form of striation perpendicular to involved bone and referred to as "sunburst" pattern.
- Cause:
 - In young patients remains unknown
 - In adults, increased incidence in association with Paget disease and postradiotherapy:
 - Referred to as secondary osteosarcomas
 - Approximately 15% to 30% occur in adults secondary to a pre-existing condition.
- Osteosarcoma in association with Paget disease:
 - More common in men
 - Overall median age in the mid seventh decade of life
 - Accounts for greater than 20% of all osteosarcomas in patients over 40 years of age
 - Most common complaint is pain of increasing severity often associated with a palpable mass
 - Approximately two thirds occur in long bones.
 - Up to 17% may occur in skull, which is most common site in the head and neck.
 - Majority arise in medulla; rare to arise on surface of bone
 - May be multifocal:
 - Occurs in up 17% of cases
 - May be superimposed on polyostotic Paget disease
 - May represent multiple primary malignancies
 - May represent metastatic spread from an index malignancy
 - Histologically most are conventional osteosarcomas with tendency to be high grade.
 - Distant metastatic disease at presentation in approximately 25% of cases
 - Poor prognosis with 5-year survival rates of <10%
- Postradiation osteosarcoma:
 - One type of sarcoma that may develop after radiation treatment (postradiation sarcoma); see Section 5, Larynx, for more complete discussion
 - Greatest risk in children treated with high-dose radiotherapy and chemotherapy
 - Prevalence increasing given increased survival after treatment of other malignancy
 - Can develop in any irradiated bone but most common in pelvic and shoulder region
 - Latent period is generally long with a median of 11 years
 - Related to radiation dosage:
 - Uncommon (approximately 0.2%) after usual therapeutic dosages in range of 7000 rads (cGy) or 70 Gy
 - Radiation doses are usually greater than 2000 Rads (cGy) or 20 Gy with most

sarcomas occurring with doses of 5500 rads (cGy) or 55 Gy or higher.

- Histology that of conventional osteosarcoma with no morphologic features distinguishing postradiation osteosarcoma from a de novo osteosarcoma:
 - Tend to be histologically high grade
- Prognosis somewhat dependent on site:
 - 68% 5-year survival for extremity lesions
 - 30% 5-year survival for those of skull and jaw bones
 - 27% 5-year survival for axial lesions
 - Prognosis worse for lesions of the pelvic, vertebral, and shoulder regions
- Other conditions/lesions that predispose to or may be associated with development of osteosarcoma include:
 - Hereditary retinoblastoma
 - Li-Fraumeni syndrome
 - Fibrous dysplasia
 - Osteoblastoma
 - Hereditary multiple exostosis
 - Ollier disease
 - Werner syndrome
 - Rothmund-Thomson syndrome
 - Congenital hypoplastic or absent thumbs

Craniofacial Conventional Osteosarcoma (Excluding in Association with Paget Disease): Gnathic Osteosarcoma (Osteosarcoma of Jaw Bones) (Figs. 6-62 and 6-63)

- Up to about 10% of conventional osteosarcomas occur in the head and neck region, with about 7% occurring in jaw bones.
- More common in men than women; occur in patients who are generally a decade or two older than those with extrafacial (i.e., long bones) osteosarcomas:
 - Mean in fourth decade
- Involvement of the mandible is more common than the maxilla:
 - Mandibular involvement in descending order of frequency includes body, symphysis, angle, and ramus.
 - Maxillary involvement in descending order of frequency includes alveolar ridge, maxillary antrum, anterior midline.
- Most common clinical complaints include:
 - For mandibular lesions: painful swelling of the face, dentition problems (toothache, loose teeth), numbness of the cheek or face
- For maxillary lesions: in addition to above may also include nasal obstruction, epistaxis, proptosis, diplopia
- Laboratory findings:
 - Not specific
 - Elevated serum alkaline phosphatase is only laboratory value of clinical import in osteosarcoma:
 - Abrupt elevation in patients with pre-existing benign bone lesion (e.g., Paget disease, other) may be indicative of malignant transformation.
- Radiology:
 - Destructive, poorly delineated osteolytic, osteosclerotic, or mixed lesion

Fig. 6-62. Osteosarcoma of the mandible.

A, Radiograph of resection specimen showing a large mass of the angle of the mandible. Multiple radiodensities representing new bone formation beneath an elevated periosteum ("sunburst" pattern) are seen. This pattern is typically associated with osteosarcoma. **B**, Corresponding gross specimen showing destruction of the mandible and extension of the tumor into adjacent soft tissue; the tumor has speculations at its peripheral portion.

Fig. 6-63. Osteosarcoma.

A, Low magnification shows a matrix-producing lesion with associated cellular proliferation including pleomorphic nuclei. **B** and **C**, Histologic features include a sarcomatous stroma intimately associated with lace-like osteoid appearing as eosinophilic, hyaline-like material with irregular contours and variable extent of dark blue-purple matrix calcification.

- Periosteal reactions include:
 - Cupping out of subperiosteal cortical bone
 - Thin, bulging, opaque, noncontinuous line of new bone formation beneath the periosteum in the adjacent soft tissue
 - Irregular, sclerotic mass of subperiosteal new bone with multiple laminations
- Codman's triangle and "sunburst" pattern (see above for descriptions) may be present but in a small percentage of cases.
- Involvement of alveolar bone between teeth may result in projection of sclerotic material beyond height of the crestal bone into adjacent soft tissue:
 - Highly suggestive of osteosarcoma
- Widening of the periodontal membrane space along one side of one or more roots is a highly characteristic feature of malignant neoplasms, including osteosarcoma:
 - Represents early radiographic finding
 - Unusual finding as most cases do not present in such early stages
- Other head and neck sites of occurrence may include:
 - Skull:
 - Represent less than 2% of head and neck osteosarcomas
 - Often occur secondary to Paget disease or previous radiotherapy to the region of involvement
 - Poor prognosis with 5-year survival rates of less than 15%
 - Larynx:
 - Rare location
 - Of bona fide examples reported in the literature, majority are extraosseous, arising in laryngeal soft tissues in and around the true vocal cords and anterior commissure
 - Poor prognosis with death usually occurring within 2 years of diagnosis

Pathology

Gross

- Dependent on the extent of mineralization versus extent of the stromal component such that the tumor may vary from firm, hard, and gritty to fleshy and fibrous
- Gnathic osteosarcomas generally do not exceed 5.0 cm in greatest diameter.

Histology

- Sarcomatous stroma intimately admixed and giving rise to osteoid
- Diagnosis is predicated on the identification of osteoid:
 - Osteoid, uncalcified precursor of bone, is a dense, eosinophilic, amorphous, hyaline-like material

- with irregular contours surrounded by a rim of osteoblasts.
 - Is refractile
 - Variable present from case to case
 - Often predisposed to “scaffolding” or appositional deposition on existing normal bony trabeculae
 - Can be difficult to differentiate from nonosseous eosinophilic extracellular materials such as collagen and amyloid:
 - Osteocalcin and osteonectin usually present in osteoid is absent in collagen and amyloid.
 - Amyloid shows apple green birefringence on Congo red staining and will be reactive for amyloid immunostains, staining patterns not seen in osteoid.
 - Stromal cells (osteoblasts):
 - May be spindle-shaped, ovoid, polygonal, round, fusiform, plasmacytoid, epithelioid, or clear with hyperchromatic nuclei with or without nucleoli
 - Display variable anaplasia but usually markedly pleomorphic and anaplastic with associated necrosis, increased mitotic activity (normal and bizarre mitoses), and invasive growth (into adjacent structures and angioinvasion)
 - Are multipotential cells capable of producing osteoid, cartilage, and collagen or fibroblastic foci; depending on which component predominates, osteosarcomas can be divided into:
 - Osteoblastic type:
 - Bone and osteoid represent the predominant matrix
 - Chondroblastic type:
 - Cartilage/chondroid matrix predominates
 - Approximately 50% of cases are chondroblastic and may be mistaken for chondrosarcoma (see later in chapter).
 - Cartilage is hypercellular and arranged in lobules; osteoid is present in center of lobules as short, poorly formed bony trabeculae or within spindle cells at periphery of lobules
 - Fibroblastic type:
 - High-grade spindle cell malignant tumor with minimal amounts of osseous matrix
 - Cartilage/chondroid matrix may or may not be present
 - In the head and neck, osteoblastic and chondroblastic are most common.
 - Prognosis not believed to correlate with above histologic subtype
 - Tumor giant cells are often seen, and benign osteoclast-like multinucleated giant cells are identified in approximately 25% of cases.
 - Vascularity varies from relatively inconspicuous to dominant.
 - Immunohistochemistry:
 - Utility of immunohistochemistry in diagnosis is limited.
 - Main use is to exclude other diagnostic considerations.
 - Osteoblasts often are vimentin and CD99 (intracytoplasmic) positive; cytokeratin and smooth muscle actin staining may be positive.
 - Osteoid is immunoreactive for osteocalcin and osteonectin in a majority of cases.
 - Cytogenetics and molecular genetics:
 - Clonal chromosomal aberrations are common but there are no specific translocations or other diagnostically significant alterations.
 - Loss of retinoblastoma (*RB1*) tumor suppressor gene common occurrence
 - p53 abnormalities common finding
- ### Histologic Variants of Osteosarcoma
- Histologic variants include:
 - Small cell:
 - Uncommon variant in the head and neck
 - Predominantly composed of small cells with variable degree of osteoid production
 - Cells have round to oval nuclei with fine to coarse chromatin and scant cytoplasm.
 - Increased mitotic activity
 - Lace-like osteoid is present but may be limited in extent and can be difficult to differentiate from collagenized stroma
 - Immunoreactivity may include CD99, vimentin, osteocalcin, osteonectin, Leu-7, and smooth muscle actin
 - *EWSR1* translocation associated with Ewing sarcoma family of tumors absent
 - Telangiectatic:
 - Rarely identified in head and neck osteosarcomas
 - Composed of prominent blood-filled cystic spaces separated by septae containing the highly malignant mononuclear neoplastic cells characterized by markedly pleomorphic cells with increased mitoses, including atypical mitoses
 - Osteoid varies in amount and tends to be fine and lacelike
 - Resembles aneurysmal bone cyst:
 - Occasionally may be solid with smaller cystic spaces
 - Cystic spaces lack endothelial cell lining and may be lined by benign-appearing giant cells.
- ### Differential Diagnosis
- As a result of the histomorphologic variability of osteosarcoma the differential diagnosis may include:

- Benign lesions, including:
 - Fracture callus
 - Myositis ossificans
 - Benign fibro-osseous lesions (fibrous dysplasia, psammomatoid ossifying fibroma, fibrous dysplasia); aneurysmal bone cyst
- Osteoblastoma
- Giant cell tumor
- Chondrosarcoma
- For small cell osteosarcoma:
 - Ewing sarcoma family of tumors
 - Other small round cell malignant tumors

Treatment and Prognosis

- Treatment for gnathic osteosarcomas is primarily surgical to include radical extirpation with tumor-free margins.
- Utility of adjuvant therapy (preoperative or postoperative radiation and/or chemotherapy) remains unclear:
 - Advocated in cases with positive margins or metastatic disease
- Regional nodal metastasis uncommon (less than 10%):
 - Neck dissections are usually not indicated.
- Overall 5-year survival rates vary in the literature, including:
 - Approximately 43%
 - 60% to 70% in other reported series
 - Earlier diagnosis and initiation of treatment are associated with a significantly better prognosis.
 - Craniofacial osteosarcomas are associated with a better prognosis than extrafacial tumors attributed to:
 - Tendency to remain localized with metastatic spread only late in the disease course
 - Lower histologic grade
- In spite of the overall better prognosis of craniofacial osteosarcomas, these are still potentially lethal tumors requiring radical management.
- Gnathic osteosarcomas prone to local recurrence:
 - Maxillary osteosarcomas recur in higher percentage of cases as compared with mandibular tumors.
 - Recurrence usually occurs within the first postoperative year.
- Metastases are uncommon and occur late in the course of disease:
 - Usually disseminate to the lungs and brain
 - Associated with a mean survival of approximately 6 months
- Prognostic factors include:
 - Positive prognostic factors include:
 - Younger age
 - Tumor-free resection margins
 - Adverse prognostic factors include:
 - Larger tumors
 - Higher grade tumors
 - Recurrent tumor
 - Developed secondary osteosarcomas

Chondrosarcoma

General Considerations

Definition: Malignant tumor of (hyaline) cartilage differentiation including chondrocytes in lacunae:

- As detailed previously, osteosarcomas may produce cartilage but lesional cells of chondrosarcomas do not produce osteoid.
 - Presence of osteoid confers a diagnosis of osteosarcoma (e.g., chondroblastic type); see below
 - In general, chondrosarcoma is one of more common primary malignant bone tumors, representing approximately 20% of all malignant bone tumors.
 - Types of chondrosarcomas:
 - Primary (conventional) chondrosarcoma arises centrally in normal bone.
 - Secondary chondrosarcoma arises in a benign precursor lesion (e.g., osteochondroma or enchondroma):
 - May occur in association with Ollier disease and Maffucci syndrome (enchondromatoses):
 - Ollier disease is a sporadically occurring developmental disorder characterized by the presence of multiple cartilaginous tumors (enchondromas, chondrosarcoma), especially of the tubular bones of the extremities.
 - Maffucci syndrome is sporadically occurring developmental disorder characterized by the presence of multiple cartilaginous tumors (enchondromas, chondrosarcoma) especially of the tubular bones of the extremities as well as cutaneous and visceral vascular tumors (hemangiomas, including spindle cell and angiosarcoma)
 - Periosteal chondrosarcoma arises on the surface of bone; also referred to as juxtacortical chondrosarcoma
 - Histologic variants of “conventional” chondrosarcoma include:
 - Clear cell
 - Dedifferentiated
 - Mesenchymal
- NOTE:** Extraskelatal myxoid chondrosarcoma is categorized by the WHO as a tumor of uncertain differentiation owing to the paucity of convincing evidence of cartilaginous differentiation:
- Characteristic translocation usually involving NR4A3 and EWSR1

Maxillofacial (Gnathic) and Skull Base Chondrosarcoma

(Figs. 6-64 and 6-65)

Clinical

- Incidence of chondrosarcoma of head and neck sites varies from 5% to 12%:
 - Most common site is the larynx (see Section 5, Larynx)
 - Other common sites of occurrence include:
 - Maxillofacial chondrosarcomas involving the craniofacial area, including the mandible, maxilla, and maxillofacial skeleton, including nasal cavity (septum, turbinates) and paranasal sinuses
 - Neuroaxial or base of skull chondrosarcomas that include base of skull and nasopharynx
- Primary conventional chondrosarcoma is most common type in the head and neck:
 - Secondary and periosteal chondrosarcomas are rare in general, especially in the head and neck.
 - Clear cell and dedifferentiated variants also are rare in general, especially in the head and neck.
- Mesenchymal chondrosarcomas also are rare but can occur in the head and neck, especially in gnathic bones but also in soft tissues of the neck (discussed later).
- Maxillofacial:
 - No gender predilection; occur over a wide age range but are most common in the fourth to fifth decades of life:
 - Approximately 2% of chondrosarcomas occur in patients less than 20 years of age.
 - Most common site of occurrence is maxilla, especially in anterior alveolar region
 - Less common in the mandible where molar region and ramus represent common sites of occurrence
- Skull base region:
 - No gender predilection; occur over a wide age range but most common in the third to sixth decades of life
 - Most arise in middle cranial fossa and much less common in the anterior fossa, posterior fossa, or middle and posterior fossae.
- Symptoms vary according to the site and include:
 - Nasal obstruction, epistaxis, changes in dentition (loosening or eruption of teeth), proptosis, visual

Fig. 6-64.

Coronal (**A**) and axial (**B**) CT scans show a bulky mass arising in the hard palate and extending ventrally into the nose. There are innumerable calcifications spread throughout the tumor. This patient had a chondrosarcoma. (From Som & Curtin: *Head and Neck Imaging*, ed 5. Philadelphia, 2011, Elsevier, Fig. 4-222, p 366.)

Fig. 6-65. Histology of chondrosarcoma.

Gnathic (mandibular) grade II (moderately differentiated) chondrosarcoma. **A**, The tumor is characterized by lobular architecture and greater cellularity than in grade I lesions. **B**, In addition to greater cellularity there is a greater degree of nuclear hyperchromasia, pleomorphism, bi- and multinucleated cells as compared with grade I tumors but not as anaplastic as seen in grade III lesions. See Section 5, Larynx, for histology of low-grade and high-grade chondrosarcomas.

disturbances and an expanding mass associated with pain, trismus, headaches, and neurologic deficits

- Radiology:
 - Poorly defined, destructive lesion with single or multiple radiolucent, radiopaque, or mixed-appearing areas, and coarse calcifications
 - CT: useful to assess tumor matrix and cortical involvement
 - MRI: useful to characterize extent of bone marrow involvement and soft tissue extension
- No known cause

Pathology

- See Section 5, Larynx, for a complete discussion of the pathologic features of chondrosarcoma.
- Histologic grading of chondrosarcomas includes:
 - Well-differentiated, or grade I:
 - Mild to moderate cellularity with relatively uniform small hyperchromatic nuclei, occasional binucleate cells, and low mitotic activity
 - Matrix varies from chondroid to myxoid.
 - Moderately differentiated, or grade II:
 - Greater cellularity than in grade I lesions with greater degree of nuclear hyperchromasia, pleomorphism/atypia, binucleate cells are frequently identified and there is increased mitotic activity (usually fewer than 2 mitoses per 10 high-power fields)
 - Matrix tends to be more myxoid than chondroid
 - Poorly differentiated, or grade III:
 - Markedly cellular with large hyperchromatic to vesicular nuclei with marked nuclear pleomorphism, prominent nucleoli, increased mitotic activity (greater than 2 mitoses per 10 high-power fields), and necrosis
 - Limited chondroid matrix
 - Irrespective of grade, lobular pattern of growth is at least focally retained.
- Immunohistochemistry:
 - No specific markers
 - Lesional cells are S100 protein, vimentin, and D2-40 (podoplanin) positive
 - Absence of staining for cytokeratins, EMA, brachyury, e-cadherin
- Cytogenetics and molecular genetics:
 - Numerous genetic abnormalities present, including (but not limited to):
 - Amplification of 12q13
 - Loss of 9p21

Differential Diagnosis

- Chondroma
- Chondroblastoma (Fig. 6-66):
 - Benign cartilage-producing neoplasm usually arising in the epiphyses of long bone of skeletally immature patients characterized by cartilaginous differentiation and presence of mononuclear cells and giant cells
 - Accounts for less than 1% of all bone tumors
 - Most common locations in femur, humerus, tibia, and tarsal bones
 - Rare in the head and neck, where the most common site is the skull and temporal bone; less common sites include mandible (condyle and angle) and maxilla

Fig. 6-66. Chondroblastoma.

A, Cellular proliferation composed of admixture of epithelioid cells with round to oval nuclei basophilic to eosinophilic cytoplasm and multinucleated giant cells.

B, Fine (lace-like) network of pericellular calcification referred to as “chicken wire calcification” is present (arrows) between mononuclear lesional cells.

- Temporal bone lesions present with mass effect, hearing loss, otalgia, and tinnitus
- Gnathic lesions present with swelling and limitation in movement.
- Histology:
 - Cellular proliferation composed of sheets of uniform, round to polygonal (epithelioid) cells with round to oval nuclei, inconspicuous to small nucleoli, and clear to slightly eosinophilic cytoplasm with distinct cell borders (chondroblasts)
 - Nuclear indentations and grooves are frequently seen.
 - Giant cells are consistently identified and include two types:
 - Numerous randomly distributed large osteoclast-type giant cells with few to numerous nuclei

- Smaller giant cells with few (2 to 3) nuclei
- Fine (lace-like) network of pericellular calcification referred to as “chicken wire calcification” consistently present but may be very focal in localization
- Chondroid differentiation is almost always present, varying from sparse to extensive and appearing as eosinophilic (rather than basophilic) matrix, within which are cells with chondroblastic differentiation; mature chondrocytes are uncommon.
- Mitotic figures are identifiable but atypical mitoses are not present.
- Aneurysmal bone cyst-like foci seen in approximately one third of cases (referred to as cystic chondroblastoma)
- Immunohistochemistry:
 - Chondroblasts are S100 protein, vimentin, and neuron-specific enolase positive.
 - Variable reactivity with epithelial markers, including cytokeratin and epithelial membrane antigen
- Conservative local excision is the preferred treatment; radiation therapy used in tumors that are difficult to excise in totality due to anatomic location.
- Local recurrence ranges from 10% to 50% and usually occurs within 2 years.
 - 50% recurrence reported in association with temporal bone lesions likely correlated to inadequate excision
- Rare examples of pulmonary metastasis of histologically benign chondroblastoma
- Synovial chondromatosis
- Chordoma (see Section 3, Pharynx) for complete discussion:
 - Chordomas are immunoreactive for cytokeratins, EMA, S100 protein, vimentin, brachyury, e-cadherin but negative for D2-40
 - Chondrosarcomas are immunoreactive for S100 protein, vimentin, and D2-40 but negative for cytokeratins, EMA, brachyury, and e-cadherin
- Osteosarcoma, chondroblastic variant (see earlier):
 - Presence of osteoid even in limited amounts confers a diagnosis of osteosarcoma and excludes chondrosarcoma.
 - Critical to examine all biopsy material or resected tissue in presence of a cartilaginous tumor of jaws

Treatment and Prognosis

- For maxillofacial chondrosarcomas:
 - Radical resection with adequate margins is indicated.
 - Usually a slow-growing but persistent tumor characterized by multiple recurrences

- Local recurrence in approximately one third of cases
- Metastases are rare.
- Overall survival rates reported include:
 - 68% at 5 years
 - 54% at 10 years
 - 44% at 15 years
- Death is generally due to uncontrolled local disease with invasion and destruction of vital structures, including intracranial extension.
- More lethal than laryngeal chondrosarcoma, perhaps because they tend to be of a histologically higher grade, but more likely due to their proximity to vital structures and difficulty in achieving negative margins
- Neuroaxial or base of skull chondrosarcomas:
 - Often are extensively infiltrative at the time of diagnosis, precluding complete resection, therefore, with a tendency for local recurrence
 - Radiotherapy can be used as an adjunct to surgery as part of the primary management of patients.
- Overall 5-year survival rate for head and neck chondrosarcoma is approximately 70%.
- Prognostic factors include:
 - Larger tumors and more central location (near maxillary sinus or mandibular ramus) associated with worse prognosis
 - Pediatric patients may have better prognosis.
- Other head and neck sites may include:
 - Sinonasal tract, oral cavity (palate) nasopharynx, soft tissues of the neck (perimandibular)
- Occurs in cranial and spinal dura mater
- Multifocality with involvement of multiple bones occurs but is rare (less than 1%).
- Most common presentation is that of pain and swelling of the affected site.
- Radiology:
 - Bone:
 - Osteolytic lesion with sharp or poorly defined margins
 - Soft tissue:
 - Plain radiographs and CT scans: well-demarcated density with sharp or poorly defined margins
 - Coarse or granular calcification often (but not always) present
 - T2-weighted MR images: depict two-component structure composed of calcified and uncalcified areas
 - Enhanced MRI: inhomogeneous enhancement in both areas

Pathology

Gross

- Circumscribed to well-defined, lobular, soft to firm, tan-white to blue-gray mass varying in size from 3 to 30 cm in greatest dimension
- Areas of hemorrhage and necrosis may be present.

Histology

- Biphasic tumor composed undifferentiated small round cells with abrupt transition with well-defined islands or nodules of (hyaline) cartilage.
- Undifferentiated small round cells:
 - Closely packed cells with uniform small, round to oval to spindle-shaped hyperchromatic nuclei and a limited amount of barely discernible cytoplasm
 - Growth patterns may include:
 - Solid (similar to the cellular infiltrate in Ewing sarcoma)
 - Alveolar or herringbone
 - Clustered with perivascular localization
- Cartilage:
 - Usually well defined, may be poorly circumscribed composed of relatively cytologically bland cartilage
 - Cartilage may appear malignant.
 - Variable in distribution appearing as large irregular areas or distinct islands admixed with the small round cell infiltrate
 - Amount of cartilage is variable from case to case; in some cases it is readily identifiable, whereas in

Mesenchymal Chondrosarcoma

(Fig. 6-67)

Definition: Rare malignant cartilaginous neoplasm (variant of chondrosarcoma) thought to originate from primitive cartilage-forming mesenchyme occurring in bone or in soft tissues composed of undifferentiated small round cells and islands of well-differentiated (hyaline) cartilage frequently associated with hemangio-pericytomatous vascular pattern.

Clinical

- Represents approximately 3% to 10% of all primary chondrosarcomas:
 - Occurs in bone and in soft tissue (extraskelatal mesenchymal chondrosarcoma)
 - More common in bone than soft tissue
- No gender predilection; occurs over a wide age range but most common in the second to third decades of life
- Common sites of involvement include craniofacial bones, especially jaw bones, orbit, and skull:
 - In head and neck, most often occur in jaws, roughly affecting the mandible and maxilla equally

Fig. 6-67. Mesenchymal chondrosarcoma.

A, Tumor showing transition from hypercellular area (*left*) to area with cartilaginous differentiation (*right*). **B**, Undifferentiated cell component shows a solid growth composed of small cells with hyperchromatic nuclei and limited cytoplasm. **C**, Cartilaginous differentiation. **D** and **E**, Another example in which limited foci of cartilage are embedded in a predominant small round cell infiltrate. **F**, Small cell component expresses CD99.

other cases requiring numerous section for identification.

- Prominent vascularity with pattern similar to that seen in hemangiopericytoma is common.
- Increased mitotic figures may be seen.
- Calcification and ossification may be present; osteoclast-like multinucleated giant cells may occasionally be present.
- Histochemistry:
 - Intracytoplasmic glycogen (diastase-sensitive, PAS-positive) may be present.
 - Reticulin stains may show envelopment of individual cells as well as clusters of cells.
- Immunohistochemistry:
 - Small round cells:
 - CD99 positive (membranous)
 - FLI1 negative
 - EMA (focally) positive (35%)
 - Desmin (focally) positive (50%)
 - May be positive for neuron-specific enolase and Leu-7
 - Cytokeratins, neuroendocrine markers, myogenin negative
 - Cartilage:
 - S100 protein positive
- Electron microscopy:
 - Evidence of dual cell differentiation, including cells with chondrocyte-like differentiation as seen in chondrosarcoma and primitive undifferentiated small cells with limited intercellular matrix
- Cytogenetics and molecular genetics:
 - *HEY1-NCOA2* [(8;8)(q21;q13)] fusion identified
 - *SOX9*, a master regulator of cartilage differentiation, expressed in mesenchymal chondrosarcoma but not other small round cell neoplasms

Differential Diagnosis

- Ewing family of tumors:
 - Presence of cartilage allows for differentiating mesenchymal chondrosarcoma from Ewing sarcoma
 - FLI1 positive in many although not all cases
 - Presence of *EWSR1* translocation, which is absent in mesenchymal chondrosarcoma
- Poorly differentiated synovial sarcoma:
 - Metaplastic cartilage may be identified but less common than foci of calcification or ossification
 - Presence of *SS18* (also known as *SYT*) translocation, which is absent in mesenchymal chondrosarcoma
- Hemangiopericytoma
- Rhabdomyosarcoma
- Malignant lymphoma
- Small cell undifferentiated neuroendocrine carcinoma

Treatment and Prognosis

- Complete surgical resection is the preferred treatment.
- Efficacy of radiation and chemotherapy in treatment remains uncertain.
- Variable clinical course:
 - Lethal over short time periods in some cases
 - Protracted clinical course with long disease-free survival in other cases
 - No difference in prognosis whether arising in bone or in soft tissues
- Tendency to local recurrence and metastasize distantly:
 - Most often to lungs and bones
 - May occur years after initial diagnosis
- Given possibility of long-term survival and late metastases, these patients require lifelong follow-up.
- Survival for all sites includes:
 - 5-year: 55%
 - 10-year: 27%
- Survival rates for gnathic tumors suggest a more indolent clinical course as compared with non-jaw-related tumors:
 - 5-year: 82%
 - 10-year: 56%
 - 15-year: approximately 38%

MALIGNANT ODONTOGENIC NEOPLASMS

- Malignant odontogenic neoplasms are rare and include odontogenic carcinomas and odontogenic sarcomas.
- Odontogenic carcinomas include:
 - Malignant ameloblastoma; see Ameloblastoma
 - Ameloblastic carcinoma (primary, secondary); see Ameloblastoma
 - Primary intraosseous squamous cell carcinoma
 - Clear cell odontogenic carcinoma
 - Ghost cell odontogenic carcinoma
 - Others
- Odontogenic sarcomas include:
 - Ameloblastic fibrosarcoma
 - Ameloblastic fibro-odontosarcoma
- Discussion of malignant odontogenic neoplasms is beyond the scope of this book, and the reader is referred to other texts entirely specializing on this topic.

SECONDARY NEOPLASMS TO THE ORAL CAVITY

- Metastatic tumor to oral cavity is rare and occurs via hematogenous spread.

- Most often occurs as part of widely metastatic disease from a known index malignant tumor:
 - May occur at presentation of primary tumor
 - May occur years after treatment for the primary tumor
- Less commonly, may represent initial manifestation of disease (i.e., occult metastasis)
- Metastases to oral cavity:
 - Most commonly occur to gnathic bones
 - Less common to soft tissues
- Virtually every conceivable malignancy may metastasize to the upper aerodigestive tract:
 - For gnathic metastases, most common primary malignant tumors include:
 - Breast, kidney, lung, prostate, thyroid, colon, other
 - For soft tissue metastases:
 - Females: breast > other
 - Males: lung > kidney, skin, others
- Immunohistochemical staining valuable in diagnosis and differential diagnosis

Secondary Neoplasms to the Oral Cavity

Intraoperative Consultation in Oral Cavity Mucosal Lesions

- Intraoperative consultative diagnosis on mucosal lesions may be performed in the setting of an untreated primary mucosal lesion or in the setting of a recurrent/persistent lesion after prior treatment (i.e., radiation and/or chemotherapy):
 - In general, intraoperative consultation should not be requested to render a primary diagnosis of a mucosal lesion.
 - Rather routinely processed biopsy material is preferred mechanism for rendering a definitive diagnosis in individuals with primary mucosal lesion
 - After biopsy diagnosis many head and neck mucosal carcinomas receive primary nonsurgical adjuvant therapy so that intraoperative consultation is not uncommon in a setting of a post-therapeutic recurrent or persistent mucosal lesion.

INDICATIONS

- Indications for intraoperative consultation of mucosal lesions of upper aerodigestive tract include:
 - Render a histologic diagnosis (e.g., carcinoma/dysplasia) to ensure adequacy when definitive therapeutic intervention is planned immediately.
 - Assessment of adequacy of resection (i.e., surgical resection margins)
 - Preliminary assessment of nature of a planned procedure based on the extent and distribution of the neoplasm (e.g., subtotal versus total resection)
 - Adequacy for diagnostic purposes
 - Determination for special handling (e.g., immunohistochemistry, flow cytometry, microbiologic cultures, other)
 - Determination of neurotropism, lymph-vascular space invasion (LVI), or bone involvement that may necessitate resection of the involved bone (e.g., mandibulectomy)
 - If lymph nodes are excised, then a frozen section may be requested to exclude the presence of metastatic disease and the need for a neck dissection.

SURGEON'S EXPECTATIONS

- Establish the diagnosis of carcinoma/dysplasia and differentiate it from lookalike lesions.

- Confirm presence or absence of lesional tissue at the margins of resection.
- When applicable, identify the presence of osseous involvement.
- When applicable, identify the presence of nodal metastasis.

SPECIMEN HANDLING AND ORIENTATION

- Evaluation of surgical margins of resection for the presence or absence of lesional tissue falls under the purview of the surgical pathologists; however, how the specimen is removed and the orientation of the specimen (Figs. 7-1 and 7-2) are the responsibility of the surgeon:
 - Particularly true for those cases in which the tumor is initially excised and the designated margins are separately removed, the tumor is removed in multiple parts or the specimen is a complex en bloc excision, requiring proper orientation by the surgeon for those margins that are of critical concern.
- Once removed and properly oriented, the specimen becomes the responsibility of the surgical pathologist.
- There is no standard method by which surgeons remove tissue and thereby request intraoperative consultation of the surgical resection margins; some approaches include:
 - Excision of the entire lesion, designation of specific margins, and tissue selection by the pathologist for frozen section
 - Circumferential resection margins are submitted for frozen section irrespective of the number of frozen sections that may be required to completely evaluate the circumferential margins.
 - A limited number of frozen sections (e.g., up to four—anterior, posterior, medial, and lateral) are submitted as determined by the pathologist.

NOTE: Anatomy of the head and neck is complex and in any given resection the risk posed by removing the entire lesion and surrounding structures for intraoperative consultation includes:

- Loss of the three-dimensional orientation of the specimen

Fig. 7-1. Resection specimen and surgical margins.

Schematic depiction of a tongue resection for carcinoma showing relationship of the resected tumor to surgical margins.

Fig. 7-2. Perpendicular versus parallel sections.

Right angle (perpendicular) versus parallel (en face) sections.

- Erroneous sampling of the areas of concern
- Submission of biopsies from areas of clinical concern after the main resection, and these biopsies are entirely submitted for frozen section.

RIGHT ANGLE (PERPENDICULAR) VERSUS PARALLEL (EN FACE) SECTIONS

- Right angle section advantages include:
 - Technically easier to obtain full thickness sections
 - Distance of the lesion to the resection margin can be viewed and measured.

- Right angle section disadvantages include:
 - Allows for evaluation of a relatively small area of the lesion/margin
- Parallel section advantages include:
 - Allows for evaluation of a larger area of the lesion/margin to include an entire margin if necessary
- Parallel section disadvantages include:
 - If the surgical margin is uninvolved, the distance of the lesion to the resection margin cannot be viewed and/or measured.
 - Due to retraction from the underlying connective tissues the superficial layers (i.e., mucosa and submucosa) may not be optimally seen.

NOTE: If parallel sections are made, the recommendation is to embed the tissue with the true surgical margin deepest in the block.

- Diagnostic accuracy for oral tongue cancer should be the same whether the sample was taken from the patient or from the surgical specimen.

SURGICAL RESECTION MARGINS

- Arguably, the most common request of the pathologist by the head and neck surgeon at the time of intraoperative consultation is assessment of the surgical margins.
- Successful local control of a malignant tumor depends on complete surgical excision of all the disease.
- Presence of gross residual cancer results in local persistence of disease and increased morbidity and mortality.

- There are many factors that affect the assessment of the surgical margins, including the type of surgical specimen, proper orientation of the specimen, proper sectioning of the specimen, and obviously the correct interpretation of the histopathologic changes.
- Unfortunately, even in the best situations an intraoperative report of negative margins may be followed a few days later by a permanent section diagnosis of positive margins.
- Probability of local recurrence in head and neck cancer is reduced when the resection margins are determined by intraoperative frozen section consultation.
- Use of intraoperative frozen sections allows the surgeon to extend the surgical resection without loss of orientation of the operative field, a potential

problem when additional surgery is required in a second operation.

- Carcinoma remnants that have not been completely removed in the initial operation often are difficult to identify macroscopically, making their removal in a second operation more difficult.
- Although the frozen section diagnosis of surgical margins is extremely accurate, it is not entirely reliable in eliminating positive margins in the final diagnostic report.

Definition of a “Positive” Margin (Fig. 7-3)

- Specimens in which no tumor or dysplasia is present at the surgical margins of resection are considered completely excised.

Fig. 7-3. Resection margins.

A, Lingual lesion showing carcinoma (*arrow*) lying within 5 mm of the resection margin (*left*) requiring additional surgical clearance of this margin. **B**, Laryngeal carcinoma lying 2 mm from the deep resection (black ink); in the larynx this amount of “clearance” is usually considered acceptable as to not require additional surgical clearance. **C**, Invasive squamous carcinoma involving the deep margin of resection (i.e., carcinoma at inked edge) in this tongue resection; additional surgical resection was required to “clear” this margin.

- “At the margin of resection” means that the neoplastic cells are seen in contact with or lie within millimeters of the pigment that was painted along the margin prior to sectioning (i.e., tumor across or up to the resection margin):
 - In this situation, the specimen is considered incompletely excised, requiring a wider excision to be assured that all viable tumor cells have been adequately removed.
- Sole reliance of margins as assessed on the resected specimen should be discouraged and, when feasible, the intraoperative evaluation of tissue surrounding the specimen should be made and regarded as the “true margin.”
- Histologic definition of what constitutes a “positive” margin should be uniformly accepted and applied:
 - Discrepancy in the literature as to what constitutes a positive or negative resection margin
 - Some authorities only include invasive carcinoma at the margin as positive, excluding carcinoma in situ, dysplasia, and gross residual disease.
 - Most pathologists would agree with the classification of positive margins as defined by:
 - Presence of lesional tissue within 0.5 mm of the surgical margin (so-called close margins) with the exception of laryngeal lesions (see later)
 - Significant dysplastic epithelium at the margin (see later)
 - Carcinoma in situ at the margin
 - Invasive carcinoma at the margin
- and often of minimal concern to head and neck surgeons.
- Given the previous statements, a two-tiered classification system can be advocated for keratinizing dysplastic lesions of the UADT, including:
 - Low-grade squamous intraepithelial lesion encompassing mild dysplasia
 - High-grade squamous intraepithelial lesion encompassing moderate dysplasia and severe dysplasia
- Relative to intraoperative consultation of mucosal dysplasia:
 - Presence of keratinizing mild dysplasia at a margin can be diagnosed as a negative margin.
 - Presence of keratinizing moderate dysplasia or keratinizing severe dysplasia at a margin is considered a positive margin.

Adequacy of Resection Margins

- Presence of invasive carcinoma and/or high-grade dysplasia within 5 mm of the inked surgical margin increases risk for local recurrence:
 - These margins are associated with approximately 80% incidence of recurrent disease so that failure of local control is not inevitable with such positive margins.
 - Absence of positive margins does not guarantee local control of disease nor is it a reliable guide to the biologic behavior of a tumor.
 - Presence of positive margins increases the likelihood of local recurrence but does not affect survival because subsequent surgery and/or irradiation may control tumor recurrence in some patients.
- Question of how wide a tumor should be excised is the responsibility of the surgeon:
 - For some specimens, such as the larynx, free margins up to 5 mm may be sufficient.
 - For a similar tumor at another extralaryngeal site, such as the oral cavity and pharynx (oropharynx, hypopharynx), wider margins (1.0 cm) are optimal.

Dysplastic Epithelium (Fig. 7-4)

- Evaluation of dysplasia under optimal circumstances (i.e., permanent sections) can be subjective, let alone at the time of frozen section, where tissue distortion and artifact create additional diagnostic difficulties potentially resulting in misdiagnoses, including overdiagnosis and underdiagnosis.
- In the upper aerodigestive tract (UADT), especially the oral cavity and larynx, the most common type of intraepithelial dysplasia is keratinizing dysplasia:
 - See Section 5, Larynx, for a discussion on keratinizing severe dysplasia.
 - In brief, keratinizing moderate dysplasia and keratinizing severe dysplasia share a similar statistical risk of progression to invasive carcinoma.
 - Therapeutic approach is similar for keratinizing moderate and severe dysplasia.
 - For all intents and purposes, keratinizing severe dysplasia is synonymous with carcinoma in situ.
 - Progression of keratinizing mild dysplasia to higher grade epithelial lesions is so low as to make this diagnosis of little clinical significance

Factors Affecting Margin Status and Prognosis (Fig. 7-5)

- More recent evidence suggests that resection margin status alone is not an independent predictor of local recurrence nor should resection margin status alone be used as the sole variable in deciding whether adjunctive radiation therapy is required; rather the need to give adjunctive radiation is suggested to be based on a variety of other parameters:
- Factors that may affect whether a margin is positive or negative, as well as in prognosis (control of

Fig. 7-4. Frozen section—surface epithelial changes.

Appearance of surface epithelium at margins of resection may include (A) normal (nondysplastic) epithelium; (B and C) mild dysplasia/reactive atypia; (D) moderate dysplasia; (E and F) severe dysplasia. In general, no additional resection is required in the face of mild (reactive) dysplasia at a surgical margin; the therapeutic approach for moderate and severe dysplasia is the same, so that if either type of dysplasia is found at the surgical margin then the surgical margin is not “clear” and additional resection, if available, may be required.

Fig. 7-5. Squamous cell carcinoma, invasive patterns.

Invasive patterns of growth in squamous cell carcinoma may include (A) invasion in well-delineated nests; (B) invasion along the advancing edge in solid cords, bands, or strands; (C) invasion in small groups or cords of infiltrating cells; (D) cellular dissociation in small groups and/or single cells.

disease) include (for more complete discussion on the following topics see previously in Chapter 6):

- Clinical stage
- Tumor size
- Positive margins:
 - Mucosal margins
 - Soft tissue margins (Fig. 7-6)
 - Mucosal margins are not the only tissue margins.
 - Surgical margins of resection may include all soft tissue components, including adipose tissue, skeletal muscle, bone, and neural structures.
 - Intraoperative assessment of osseous margins is difficult given the inherent difficulties in performing frozen section on bone.
 - Touch preparations or imprints of the cancellous bone of the stump or frozen sections of curetted material can be

performed and have shown varying degree of success.

- Alternatively, a portion of the soft tissue immediately adjacent to the periosteum may be submitted for frozen section. If negative this might indicate that there is sparing of the bone and if positive would indicate that there is bone involvement. However, the evaluation of the nonosseous soft tissue is not a reliable indicator vis-à-vis osseous involvement; in irradiated mandibles it may not be possible to separate the periosteum.
- Histologic risk assessment that includes score based on:
 - Pattern of invasion:
 - Histologic assessment results in stratification of patients into low-risk, intermediate-risk, and high-risk categories that define

Fig. 7-6. Perineural invasion.

A, Frozen section showing perineural invasion, which may alter the intraoperative surgical approach and necessitate excision of additional nerves. **B**, Permanent section confirming the intraoperative diagnosis of neurotropism.

recommendations for adjuvant radiotherapy (see Table 6-4):

NOTE: In practice, the histologic assessment of the patterns of invasion is not considered a standard of practice and most pathologists do not render such an evaluation on intraoperative consultation or even in permanent sections.

Tissue Shrinkage and Surgical Margins

- Reliability of measuring the resection margins is affected by postremoval changes especially related to tissue shrinkage.

- It is obvious that obtaining adequate tumor-free surgical margins is critical for the successful management of the cancer patient.
- Disparate surgical margin lengths of resected specimens between the in vivo measurements by the surgeon and the in vitro measurements by the pathologist occur in head and neck resection specimens:
 - Mean tissue shrinkage of 31% from the initial in situ measurement by the surgeon to the final microscopic assessment of oral cavity and lingual surface mucosal margins by the pathologist has been reported.
 - To obtain 5 mm of histopathologically clear margin, an in situ margin of resection of at least 8 to 10 mm must be taken.
 - Relative to oral squamous cell carcinomas a reduction of 46% from the planned surgical margin before resection to the microscopically measured margin after pathologic preparation has been reported:
 - Minimum of 10-mm measured in situ surgical margin and average of 5.8 mm margin after fixation
 - Significant differences in the longitudinal diameter of the whole specimen from in situ to fresh states and in the diameter of the tumor from the fresh state to fixed states with the most significant shrinkage reported from the fresh state to the fixed state with a mean shrinkage of 4.82 mm.
- It is apparent that a significant amount of tissue shrinkage occurs from the moment the tissue is excised to the time the pathologist reviews the histologic preparation of the excised tissues; such tissue shrinkage should be taken into account and accommodated for by the surgeon at the time of the operation.

DIFFERENTIAL DIAGNOSIS OR PITFALLS IN THE INTRAOPERATIVE ASSESSMENT OF SQUAMOUS CELL CARCINOMA, INCLUDING INTRAEPITHELIAL DYSPLASIA AND INVASIVE CARCINOMA

- Frozen section consultations on mucosal surface lesions can be useful, especially in differentiating inflammatory and neoplastic lesions.
- Histologic grading of a mucosal malignancy (i.e., squamous cell carcinoma) may be problematic and is not advocated by frozen section.

- Artfactual distortion and sampling limitations may lead to erroneous conclusions relative to the histologic differentiation of the carcinoma.
- Lookalike lesions of squamous cell carcinoma and/or dysplasia may include reactive epithelial changes, postirradiation changes, and the juxtaoral organ of Chievitz.

Reactive Epithelial Changes

- Reactive, infectious, and neoplastic lesions (e.g., granular cell tumor) may be associated with an exuberant epithelial response (pseudoepitheliomatous hyperplasia [PEH]) that may be mistaken for squamous cell carcinoma.
- Despite this marked epithelial proliferation, there typically is an absence of significant cytomorphic atypia and evidence of invasion with associated

tissue response (i.e., desmoplasia), allowing for differentiating PEH from squamous carcinoma.

Postirradiation Changes

(Figs. 7-7 through 7-9)

- See Section 5, Larynx, for additional discussion and images.
- Postirradiation alterations may lead to false-positive diagnosis due to the presence of bizarre cytologic alterations in the epithelium, minor salivary glands, fibroblasts, skeletal muscle, and endothelial cells.
- Distinguishing invasive squamous cell carcinoma from radiation change is challenging.
- Knowledge of prior radiation treatment is imperative in the evaluation of a given specimen:

Fig. 7-7. Postirradiation atypical fibroblasts.

A and B, May appear as individual cells in scar formation or inflammatory tissue with “smudged”-appearing nuclei lacking cohesive cellular groupings. **C and D,** In contrast, foci of squamous cell carcinoma typically appear in cohesive cellular groupings.

Fig. 7-8. Postirradiation squamous metaplasia of minor salivary glands (sialometaplasia).

A, At low magnification a key feature of sialometaplasia is the retention of the lobular architecture of the involved minor salivary glands (*arrows*). **B** and **C**, At higher magnification the features of the metaplastic foci may potentially be confused with invasive squamous cell carcinoma, making the low magnification features showing retention of lobular architecture a key diagnostic feature in rendering the correct interpretation; note residual mucocyte in panel **C** (*arrow*).

- Such information should routinely be provided by the clinical team to the pathologist(s) performing the intraoperative consultation.
- If this information is known prior to surgery and the intraoperative consultation, comparison of any previous material (e.g., biopsy) with the frozen section under review would be beneficial.
- Differentiation of radiation effect versus squamous cell carcinoma is based on histologic review.
- Postirradiation changes can be divided into acute and chronic alterations:
 - Acute postirradiation phase:
 - Days to weeks after radiation
 - Biopsies are seldom obtained
 - Later postirradiation period:
 - 6 to 7 weeks after therapy to years later
 - Show variable histologic changes, including:
 - Thinner than normal surface epithelium
 - Surface ulceration
 - Squamous epithelial atypia
 - Atrophy of minor salivary gland acini
 - Pseudoepitheliomatous proliferation of the surface epithelium
 - (Atypical) squamous metaplasia (sialometaplasia) of minor salivary glands:
 - Retention of lobular architecture/configuration of minor salivary glands supports benign (reactive) changes and not presence of invasive carcinoma irrespective of the cytologic atypia.
 - Conversely, effacement of the lobular architecture would support a diagnosis of carcinoma.

Fig. 7-9. Postirradiation soft tissue changes.

Additional postirradiation changes may include (**A**) bizarre-appearing skeletal muscle, which can be confused with invasive squamous carcinoma; (**B** and **C**) vascular alterations, including myointimal proliferation with enlarged and atypical appearing endothelial cells.

- Submucosal fibrosis
- Vascular alterations characterized by telangiectatic capillaries often with prominent (plump) endothelial cells, myointimal proliferation, foamy histiocytes within the intima and thrombosis
- Atypical (bizarre) stromal fibroblasts:
 - Often appears as individual cells with “smudged”-appearing nuclei, supporting diagnosis of radiation-associated atypical fibroblasts in scar tissue or inflammatory tissue rather than the cohesive pattern of growth that can be seen in association with invasive carcinoma
- Bizarre striated muscle degeneration
 - Delayed radiation injury generally is not characterized by cellular inflammatory infiltrate.
- Familiarity with these findings should allow for their recognition and prevent misinterpretation.

Juxtaoral Organ of Chievitz (Fig. 7-10)

- See Chapter 4 in this section.
- Normal microscopic structure of unknown function located bilaterally at the angle of the mandible (in the retromolar trigone of the oral cavity) near the buccotemporalis fascia and intimately associated with branches of the buccal nerve
- Histologically, this structure is composed of nests or clusters of squamous cells with intercellular bridges surrounded by basaloid cells; the latter may show nuclear palisading:
 - Keratinization is not present, although duct-like lumina may be seen.
 - Cells are uniform with low nuclear-to-cytoplasmic ratio, minimal pleomorphism, and absent mitotic figures; desmoplasia is absent.

Fig. 7-10. Juxtaoral organ of Chievitz.

Juxtaoral organ of Chievitz is a normal microscopic structure of unknown function located bilaterally at the angle of the mandible (in the retromolar trigone of the oral cavity) near the buccotemporalis fascia and intimately associated with branches of the buccal nerve. **A-D**, Histologically, round nests of squamoid (epithelial) cells within a fibroconnective tissue stroma are identified; the cells are nonkeratinizing composed of uniform, bland-appearing nuclei with low nuclear-to-cytoplasmic ratio, minimal pleomorphism and absent mitotic figures; desmoplasia is absent. These structures represent an incidental finding at frozen section and normally may be intimately associated with small peripheral nerves (branches of the buccal nerve). Awareness of their presence and association with nerves allow for accurate interpretation and not misinterpretation as invasive neurotropic squamous cell carcinoma.

- These structures may easily be misinterpreted as invasive carcinoma with perineural invasion; familiarity with these structures, their characteristic location, and overall relatively bland histomorphology should allow for distinguishing these normal benign structures from invasive carcinoma.
- Communication with the surgeon would be imperative in identifying these structures and not misdiagnosing them as invasive carcinoma.

CONTRAINDICATIONS

- As with any surgical procedure, there are contraindications for the utilization of frozen sections (Fig. 7-11).
- Frozen section consultation should not be used:
 - When frozen section diagnosis will not have any impact on surgery and/or impact on additional (immediate) decision:
 - Contraindicated to satisfy curiosity of surgical team
 - If tissue specimen is small and additional sampling is not planned:
 - Findings in frozen section may be equivocal, and/or material is artifactually distorted by the frozen section technique, hampering histologic evaluation after routine (permanent) sections.
 - For heavily calcified or ossified tissue
 - For certain lesions such as small cutaneous melanocytic lesions and lymphoproliferative lesions requiring special handling or extensive histologic evaluation for diagnosis

Fig. 7-11. Questionable use of frozen section.

Biopsy of a vocal cord keratotic lesion sent for frozen section. **A**, The tissue sample is small and includes the presence of an exophytic epithelial proliferation with marked keratosis. **B**, In the depth of the lesion there is a (focal) basal zone atypia with scant submucosa present. The request to perform a frozen section on this sort of lesion is of questionable utility; the specimen is inadequate for diagnosis given the limited stromal tissue, the surgeon had no intention of performing any additional resection based on the intraoperative consultation findings, and the freezing artifact potential compromises the ability to render a definitive diagnosis on permanent sections. This can be considered inappropriate use of frozen section and is a scenario that a frozen section should be declined in lieu of sending the tissue for routine (permanent) section.

INTRAOPERATIVE RAPID IMMUNOHISTOCHEMICAL ASSESSMENT

- Intraoperative immunohistochemical assessment consisting of touch smear cytologic preparations and cytokeratin staining in 20 minutes from the time of tissue sampling
- Not routinely used in setting of intraoperative consultations
- Limited studies to date in general and none relative to mucosal margins of the upper aerodigestive tract

MOLECULAR BIOLOGY IN THE ASSESSMENT OF SURGICAL MARGINS ("MOLECULAR MARGINS")

- Previous studies have shown some utility of molecular biologic markers in assessment of intraoperative consultation material including:
 - p53 mutations:
 - Presence of p53 mutations in surgical margins and in lymph nodes negative for tumor by light microscopic examination portended a substantially higher risk of local recurrent disease than those patients without p53 mutations in their surgical specimens

- Suggestion that molecular biologic studies may augment conventional light microscopy in identifying cancer at surgical margins and in lymph nodes and may improve the prediction of local tumor recurrence
- eIF4E is a translation initiation factor and powerful oncogene when overexpressed in model cell lines:
 - eIF4E reported to be elevated in head and neck squamous cell carcinoma (HNSCC) but not in benign lesions and overexpression of eIF4E may represent an early step in malignant transformation
 - Immunohistochemical analysis for eIF4E expression shown to be consistently elevated in patients with SCC:
 - In patients with laryngeal and hypopharyngeal carcinoma:
 - Absence of eIF4E in histologically negative surgical margins associated with absence of locoregional recurrences
 - Overexpression of eIF4E in the surgical margins associated with local recurrence; disease-free interval of 31.95 months
 - Significant differences in the Kaplan-Meier survival curves reported for eIF4E-positive and eIF4E-negative margins
- "Molecular margins" not presently used in setting of intraoperative consultations or in assessing histopathologic negative surgical margins and negative lymph nodes for patients with HNSCC nor has it

supplanted conventional methods of evaluating surgical resection margins

ACCURACY

- In general, the accuracy of frozen section diagnosis in head and neck surgery is high, and when deferred diagnoses are excluded, the reported accuracy ranges from 97% to 99%.
- Several errors and other factors may account for any potential discrepancies in the frozen section-to-permanent section diagnosis.
- Errors can be divided into four categories, including:
 - Sampling errors
 - Interpretative errors
 - Technical errors
 - Communication errors
- Other factors that may influence the result of a frozen section, including (but not limited to):
 - Cooperation between the surgeon and pathologist
 - Quality assurance program allowing for continuous analysis and critical overview of the frozen section standards
 - Availability of other pathologists for consultation in challenging cases
 - Availability of technically competent staff
 - Equipment

LYMPH NODES

- Frozen section diagnosis of lymph nodes is considered to be extremely accurate.
- An accuracy rate of approximately 99%, excluding deferred diagnoses, reported with a 0.1% false-positive rate and a 1% false negative rate.
- Lymph nodes represent the most frequently deferred specimen in frozen section diagnosis, especially in the diagnosis of a lymphoma.
- In general, the diagnosis of a carcinoma in a lymph node is not problematic at frozen section.
- Lymph node frozen section has also been used for accurate staging of the head and neck patient.

Sentinel Lymph Nodes in Head and Neck Squamous Cell Carcinoma

- There is increasing literature documenting the efficacy of sentinel lymph node evaluation in patients clinically staged as T1/T2,N0,M0 with diagnostic accuracy of more than 90% and with few reported false negatives.
- Elective treatment of cN0 necks by surgery and/or irradiation is controversial; some authorities

advocate a conservative (watch-and-wait) approach and other authorities advocate treatment.

- Overall risk of occult metastases or neck recurrence in cN0 necks ranges from 10% to 30%, prompting arguments for and against elective treatment.
- Majority of patients with cN0 necks likely do not harbor occult metastases, but patients with undetected and untreated metastases will experience high failure rates with increased morbidity and mortality; for this reason, sentinel lymph node procedure is gaining more support in the treatment of cN0 necks.
- Studies of sentinel lymph node procedure in head and neck squamous cell carcinoma have shown:
 - A sensitivity of greater than 90% in identifying at least one sentinel lymph node
 - False-negative rate of less than 10% (mean, 3.2%)
 - Clinical significance of identifying micrometastatic disease (i.e., isolated tumor cells and/or clusters of tumor cells measuring less than 0.2 mm as defined in breast cancer) relative to HNSCC remains to be clarified but likely is significant in its prognostic import.
 - Suggest that both the number and position of positive sentinel nodes may identify different prognostic groups that may allow further tailoring of management plans
- Conceptually, lymphatic drainage from a specific anatomic site is assumed to be predictable in the lymphatic drainage; therefore metastatic tumor cells from a specific location will become deposited into the first (sentinel) node in a lymph node chain.
- Pathologic work-up, including handling of the gross resection specimen, number of histologic sections, use of special stains (i.e., immunohistochemistry) for the sentinel lymph node procedure for head and neck squamous cell carcinoma has not to date been standardized.
- Application of sentinel lymph node procedure to head and neck squamous cell carcinoma has not as yet reached the level of standard of patient care.
- Further studies are warranted before considering this technique to be the “gold standard” in patients with oral squamous cell carcinoma and a negative neck by clinical examination and imaging studies.

Embryology, Anatomy, and Histology of the Pharynx

PHARYNX

- 12- to 14-cm long musculomembranous tube shaped like an inverted cone
- Extends from the cranial base to the lower border of the cricoid cartilage (level of the sixth cervical vertebra)
- Limited superiorly by the posterior part of the body of the sphenoid and basilar part of the occipital bone and inferiorly with the esophagus, to which it is continuous
- Lies behind and communicates with the nasal, oral, and laryngeal cavities via the nasopharynx, oropharynx, and hypopharynx (laryngopharynx),

respectively; on this basis the pharynx is divided into three anatomic divisions including (from superior to inferior): (Fig. 8-1)

- Nasopharynx
- Oropharynx
- Hypopharynx:
 - Often included as part of the larynx but given differences in embryology from the larynx (see Section 5) and the inclusion of hypopharyngeal cancers in the AJCC staging of pharyngeal cancers and not laryngeal cancers, the hypopharynx including the piriform sinus is included in this section on the Pharynx rather than in Section 5, Larynx.

Fig. 8-1. Regions of the pharynx.

- Pharyngeal lining mucosa is continuous with the mucosa lining the nasal cavity, oral cavity, pharyngotympanic (eustachian) tubes, and larynx.

EMBRYOLOGY OF THE PHARYNX

- Primitive pharynx is derived from the foregut developing from the branchial arches and pharyngeal pouches:
 - Epithelium and glands are of endodermal derivation.
 - Tonsils develop from the second pharyngeal pouch.
 - Tubotympanic recess (forms the eustachian tube and tympanic cavity) develops from the first pharyngeal pouch.
 - Lymphoid tissues of the pharynx, including adenoids (pharyngeal tonsil), lateral pharyngeal lymphoid bands, and lingual and palatine tonsils, arise from pharyngeal endoderm.
 - Constrictor muscles derived from the fourth and sixth branchial arch

CONTENTS OF THE PHARYNX

Nasopharynx

- Nasopharyngeal tonsils (adenoids) lie along the posterior and lateral aspects of the nasopharynx.
- Orifice of eustachian tube lies along the lateral aspects of the nasopharyngeal wall.

Oropharynx

- Soft palate
- Base of tongue, including the lingual tonsils
- Tonsillar pillars
- Palatine tonsils
- Posterior tonsillar pillars
- Uvula
- Waldeyer tonsillar ring (Fig. 8-2) is formed by a ring or group of extranodal lymphoid tissues about the upper end of the pharynx, which consists of the:
 - Palatine tonsils
 - Pharyngeal tonsils (adenoids)
 - Base of tongue/lingual tonsils
 - Adjacent submucosal lymphatics

Fig. 8-2. Waldeyer tonsillar ring.

ANATOMIC BORDERS OF THE PHARYNX

Nasopharynx

- Situated behind the nasal cavity and above the soft palate, it begins anteriorly at the posterior choana and extends along the plane of the airway to the level of the free border of the soft palate.
- Anterior: continuous with the nasal cavities through the choanae
- Posterior: continuous with the roof and is further supported by first cervical vertebra (anterior arch of the atlas)
- Superior (roof): base of skull (occipital bone) and posterior part of the body of the sphenoid bone
- Inferior (floor): continuous with the oropharynx; during swallowing, the palate and uvula provide a functional floor
- Lateral: each side contains the pharyngeal orifice of the eustachian tube, which in the posterior portion has a submucosal cartilaginous elevation called the torus tubarius, behind which is a shallow depression called the fossa of Rosenmüller.

Oropharynx

- Portion of continuity with the pharynx extending from the plane of the superior surface of the soft palate to the superior surface of the hyoid bone (or floor of the ventricle)
- Anterior: continuous with the mouth through the oropharyngeal isthmus
- Posterior: on a level with the second and third cervical vertebrae
- Superior: horizontal plane of the palate
- Inferior: horizontal plane of the hyoid bone (upper border of the epiglottis)
- Lateral: palatopharyngeal arch

HYPOPHARYNX

Anatomic Borders

- Superior border: just above the level of the hyoid bone
- Inferior border: lower border of the cricoid cartilage
- Anterior border: mucosa on the medial surface of the thyroid cartilage
- Posterior and lateral border: no markings; lateral walls attach to the hyoid bone and thyroid cartilage
- Medial border: larynx and its appendages
- Piriform sinus: (Fig. 8-3)

Fig. 8-3. Hypopharynx including the piriform sinus.

- Represents part of the hypopharynx that expands bilaterally and forward around the sides of the larynx and lies between the larynx and the thyroid cartilage
- Synonymous with piriform recess and piriform fossa
- Piriform means pear-shaped from Latin *pirum*, “pear,” and *forma*, “shape.”
- Pyriform means flame-shaped from Greek *pyra*, “fire.”
- Piriform sinus is pear shaped and not flame shaped; although both spellings have been used for this anatomic site, the correct spelling based on anatomic shape is piriform.

Innervation

- Both motor and sensory innervation are primarily supplied from the pharyngeal plexus formed by branches of cranial nerves IX (glossopharyngeal) and X (vagus).

Vascular Supply and Lymphatic Drainage

- Arteries and veins:
 - Naso- and oropharynx:
 - Arterial supply comes from branches of the external carotid artery, including the ascending pharyngeal, facial, lingual, maxillary, and superior thyroid arteries.

- Veins form a plexus that drains into the internal jugular and facial veins directly or via a communication with the pterygoid venous plexus.
- Hypopharynx:
 - Arterial supply from branches of the superior and inferior thyroid artery branches of the carotid artery and the subclavian artery, respectively
 - Venous plexus communicates with the pterygoid plexus above and the superior thyroid and lingual veins below or directly with the facial vein or the internal jugular vein.
- Lymphatics:
 - Nasopharynx:
 - Directly to the upper deep cervical lymph nodes
 - Oropharynx, including the tonsil and base of tongue:
 - Upper deep cervical lymph nodes particularly to the jugulodigastric and jugulo-omohyoid group of lymph nodes
 - Hypopharynx:
 - Drain to the lymph nodes of the deep cervical chain

HISTOLOGY OF THE PHARYNX

Nasopharynx (Fig. 8-4)

- Epithelium varies from stratified squamous in the lower and posterior regions to ciliated pseudostratified (respiratory) columnar type near the choanae and adjacent roof of the nasopharynx to intermediate (“transitional”) type in the junctional zones in the roof and lateral walls:
 - Intermediate (“transitional”) epithelium seen at junction between squamous and respiratory type epithelium (similar epithelium identified in the larynx)
 - Basaloid nuclei with minimal cytoplasm may raise concern for intraepithelial dysplasia:
 - Presence of smooth rather than coarse nuclear chromatin, smooth rather than irregular nuclear contours, and generally limited nuclear pleomorphism and absence of increased mitotic activity should allow distinction from intraepithelial dysplasia.
 - Isolated focus or foci of intraepithelial dysplasia occurring in the absence of an invasive carcinoma is rarely seen:
 - Unlike the oral cavity and glottic portion of the larynx, where intraepithelial dysplastic lesions may result in clinical symptoms warranting biopsy, intraepithelial dysplasia(s) of the pharynx typically does not engender clinical symptoms, so it is extremely uncommon

for the pathologist to identify isolated intraepithelial dysplastic alterations of the pharynx without its being seen in association with invasive carcinoma.

- More likely, when confronted with histologically suspicious foci for intraepithelial dysplasia in a routine specimen from a structure in the nasopharynx, it is likely intermediate (“transitional”) epithelium.
- Although these types of epithelia may be associated with a specific part of the nasopharyngeal region, this is not constant so that any site may be covered by any type of epithelium.
- Submucosa contains minor salivary glands as well as a prominent lymphoid component.
- Nasopharyngeal tonsils, also known as the adenoids, represent extranodal lymphoid tissues characterized by:
 - Epithelium infiltrated by many small lymphoid cells (so-called lymphoepithelium, Fig. 8-5) expanding and disrupting the epithelium to produce a reticulated pattern:
 - Blurred interface between epithelium and submucosa, including lymphoid cells
 - Basaloid-appearing cells with uniform, vesicular nuclei
 - Typically lack keratinization but abrupt areas of keratinization may be present
 - Epithelial component is cytokeratin positive
 - In nonendemic populations, normal nasopharyngeal mucosa is typically negative for the presence of Epstein-Barr virus
 - Presence of germinal centers but absence of a capsule, sinusoids, or epithelial crypts

Oropharynx (Figs. 8-6 and 8-7)

- Epithelium throughout is a stratified squamous epithelium, which normally does not have a keratin layer.
- Submucosa contains:
 - Minor salivary glands, which are mixed seromucous glands but are predominantly mucous
 - Scattered lymphoid component
- Palatine and lingual tonsils, like the adenoids, contain:
 - A prominent lymphoid component, including germinal centers but does not have a capsule or sinusoids
 - Unlike the adenoids, the palatine and lingual tonsils have 10 to 20 (tonsillar) crypts formed by invagination of the free surface mucosa, are narrow tubular epithelial diverticuli branching within the tonsils, and are frequently packed with plugs of shed epithelial cells, lymphocytes, and bacteria, which may calcify:

Fig. 8-4. Normal nasopharyngeal histology. Nasopharyngeal “lymphoepithelium.”

Areas of the nasopharynx are lined by (A) nonkeratinizing stratified squamous epithelium or (B) ciliated columnar (respiratory) type epithelium; mucocytes are present. C and D, Intermediate (“transitional”) epithelium lying between squamous and respiratory type epithelium characterized by cells with basaloid nuclei, smooth nuclear contours, and limited nuclear pleomorphism with absent increased mitotic activity. Note preservation of surface cilia. Such features should allow for distinction from intraepithelial dysplasia, the latter rarely seen as an isolated finding in nasopharyngeal biopsies in the absence of an invasive carcinoma. E, Nasopharyngeal tonsils also referred to as adenoids represent extranodal lymphoid tissues lined by squamous epithelium and submucosal lymphoid cell population including germinal centers; there is polar distribution of mantle lymphocytes with orientation toward the surface epithelium.

Fig. 8-5.

A, Nasopharyngeal “lymphoepithelium” characterized by basaloid appearing cells with uniform, vesicular nuclei infiltrated by small lymphoid cells expanding and disrupting the epithelium and producing a reticulated pattern. **B**, At higher magnification the epithelial cells are composed of uniform, vesicular nuclei and small eosinophilic nucleoli; rare mitotic figures can be identified (*arrow*). **C**, Cytokeratin (AE1/AE3) staining highlights the epithelial cells, whereas the lymphoid cells lack cytokeratin staining. **D**, In nonendemic populations, the nasopharyngeal mucosa is negative for the Epstein-Barr virus (in situ hybridization for Epstein-Barr encoded RNA).

Fig. 8-6. Oropharyngeal tonsils.

A, At low magnification the nasopharyngeal tonsils (adenoids) are lined by a surface nonkeratinizing squamous epithelium that, unlike the nasopharyngeal tonsils (adenoids), include tonsillar crypts formed by invagination of the surface mucosa appearing as narrow tubular epithelial diverticuli branching within the tonsils frequently containing actinomycotic colonies (*center of image*). **B**, Higher magnification of the actinomycotic colonies (so-called sulfur granules) representing commensal microorganisms normally found within tonsillar crypts. Surrounding the bacterial colonies are shed epithelial cells and lymphocytes.

Fig. 8-7. Tonsillar crypt reticulated epithelium.

A, As the stratified squamous epithelium of the tonsillar surface (*upper right*) extends into the tonsillar crypts, a dense lymphoid infiltrate penetrates the reticulated epithelium (*arrows*), obscuring the junction between epithelial and lymphoid components; like the adenoids, the palatine and lingual tonsils contain a submucosal prominent lymphoid component, including germinal centers with orientation of the mantle lymphocytes toward the surface epithelium. **B**, The basal lamina of reticulated epithelium is discontinuous and porous, facilitating migration of mature lymphocytes and plasma cells (and dendritic cells) penetrating the reticulated epithelium obscuring the junction between epithelial and lymphoplasmacytic components. **C**, Reticulated epithelial cells are basaloid appearing with vesicular nuclei, increased nuclear-to-cytoplasmic ratio, absence of keratinization, absence of intercellular bridges, and loss of distinct cytoplasmic border. **D**, Cytokeratin (AE1/AE3) staining highlights the epithelial cells, whereas the lymphoplasmacytic cell infiltrate lacks cytokeratin staining. **E**, p16 immunoreactivity seen in normal (non-neoplastic) tonsillar crypt epithelium is not evidence for the presence of HPV-associated intraepithelial dysplasia and/or carcinoma.

- Actinomycotic colonies (*Actinomyces israelii*) are commensal microorganisms that may be found within tonsillar crypts.
- Tonsillar crypts are lined by specialized stratified squamous epithelia known as reticulated epithelia, which:
 - Lack the orderly laminar structure of the surface-stratified squamous epithelia of the tonsils, including loss of cellular polarity and surface maturation
 - As stratified squamous epithelium of the tonsillar surface extends into the tonsillar crypts a dense lymphoid infiltrate, as well as macrophages, penetrates the reticulated epithelium obscuring junction between epithelial and lymphoid components:
 - Basal lamina of reticulated epithelium is discontinuous and therefore porous, facilitating migration of lymphocytes and dendritic cells, the latter representing potent antigen processing cells.
 - Intimate association of epithelial cells and lymphocytes facilitates direct transport of antigen (e.g., HPV, HIV) from external environment to the tonsillar lymphoid cells:
 - Reticulated epithelial cells are functionally similar to microfold (M) cells of the gut.
 - Lymphoid tissue elsewhere depends on direct antigen delivery through afferent lymphatic vessels but such afferent vessels are absent from the tonsils.
 - Total surface area of the reticulated epithelium is very large owing to the complex branched nature of the tonsillar crypts.
 - Reticulated epithelium is characterized by numerous (intraepithelial) blood vessels that can be further delineated by vascular endothelial cell immunomarkers (e.g., CD31, others).
- Metastatic carcinomas to the cervical neck may originate from very small crypt carcinomas that histologically appear to be wholly confined to the crypt epithelium without apparent evidence of invasion into the submucosa.
 - Reticulated epithelial cells are basaloid appearing with vesicular nuclei, increased nuclear-to-cytoplasmic ratio, absence of keratinization, absence of intercellular bridges, and loss of distinct cytoplasmic border.
 - HPV-associated squamous cell carcinomas originating from tonsillar crypt epithelium are nonkeratinizing and may be viewed as “poorly differentiated”; however, such cancers are in fact differentiated, originating and recapitulating the features of its cell of origin being that of the specialized tonsillar crypt reticulated epithelium.
 - p16 immunoreactivity may be seen in normal (non-neoplastic) tonsillar crypt epithelium and is not evidence for the presence of HPV-associated intraepithelial dysplasia and/or carcinoma.
- Minor salivary glands of the palatine tonsils (as well as the uvula and soft palate) are mixed seromucous but are predominantly mucous and can be seen embedded in the underlying muscle.
- Minor salivary glands at the lingual tonsils/base of the tongue are pure mucous type.

NOTE: The discontinuous basal lamina of the reticulated epithelium coupled to the numerous intraepithelial blood vessels assist in explaining the facts that:

- Any carcinoma arising from the crypt epithelium should be interpreted as invasive carcinoma rather than carcinoma in situ.

Hypopharynx

- Epithelium is nonkeratinizing stratified squamous epithelium.
- Seromucous glands are seen throughout the submucosa.
- Not characterized by “lymphoepithelium” or reticulated epithelium

Neoplasms of the Sinonasal Tract

CLASSIFICATION OF NEOPLASMS OF THE NASAL CAVITY AND PARANASAL SINUS (Table 3-1)

BOX 3-1 Classification of Neoplasms of the Sinonasal Tract

Benign Neoplasms

Epithelial

- Schneiderian papillomas
- Squamous papilloma (nasal vestibule)
- Minor salivary gland neoplasms

Mesenchymal/Neuroectodermal

- Lobular capillary hemangioma (pyogenic granuloma)
- Sinonasal glomangiopericytoma (formerly sinonasal-type hemangiopericytoma)
- Sinonasal tract meningioma
- Ectopic pituitary adenoma
- Solitary fibrous tumor
- Benign peripheral nerve sheath tumor
- Benign fibrous histiocytoma
- Leiomyoma
- Rhabdomyoma
- Osteoma
- Fibro-osseous lesions (ossifying fibroma, juvenile active ossifying fibroma)
- Chondroma
- Myxoma/fibromyxoma/chondromyxoid fibroma
- Ossifying and nonossifying fibromyxoid tumor
- Ameloblastoma
- Others

Malignant Neoplasms

Epithelial

- Squamous cell carcinoma:
 - Keratinizing squamous cell carcinoma
 - Nonkeratinizing squamous cell carcinoma

- Variants of squamous cell carcinoma (verrucous carcinoma, papillary squamous cell carcinoma, spindle cell squamous carcinoma, basaloid squamous cell carcinoma, lymphoepithelial carcinoma, adenosquamous carcinoma)
- Sinonasal undifferentiated carcinoma
- *SMARCB1* (INI1)-deficient carcinoma
- NUT midline carcinoma
- HPV-associated adenoid cystic-like carcinoma
- Adenocarcinoma:
 - Salivary gland types
 - Intestinal types
 - Nonsalivary, nonintestinal types

Mesenchymal/Neuroectodermal

- Olfactory neuroblastoma
- Neuroendocrine carcinomas
- Mucosal malignant melanoma
- Non-Hodgkin malignant lymphomas
- Ewing family of tumors
- Undifferentiated pleomorphic sarcoma
- Fibrosarcoma
- Leiomyosarcoma
- Malignant schwannoma
- Angiosarcoma
- Matrix-forming malignant tumors (osteosarcoma, chondrosarcoma)
- Low-grade sarcoma with neural and myogenic differentiation (LGSSNMF)
- Teratocarcinosarcoma
- Secondary tumors

GENERAL CONSIDERATIONS

- The sinonasal tract is the location for a wide variety of benign and malignant tumors.
- The more common tumor types are of epithelial origin and include:
 - Benign neoplasms: Schneiderian papillomas
 - Malignant neoplasms: squamous cell carcinoma and variants thereof
- Whether benign or malignant, neoplasms of the sinonasal tract often present with nasal obstruction,

which may also be the clinical presentation for non-neoplastic lesions:

- Presence of pain and/or manifestations of cranial nerve dysfunction is an indicator of a malignancy until proven otherwise.
- Clinical information is paramount for the pathologist to evaluate any given case.
- Carcinomas of the sinonasal tract account for less than 1% of all malignant neoplasms.
- Carcinomas of the sinonasal tract account for approximately 3% of head and neck malignant neoplasms.

- Based on the entire sinonasal tract, malignant neoplasms originate (in descending order of occurrence) from:
 - Maxillary sinus (60%)
 - Nasal cavity (20% to 30%)
 - Ethmoid sinus (10% to 15%)
 - Sphenoid and frontal sinuses (1%)
- Based on the entire paranasal sinuses alone, malignant neoplasms originate (in descending order of occurrence) from:
 - Maxillary sinus (77%)
 - Ethmoid sinus (22%)
 - Sphenoid and frontal sinuses (1%)
- Cause of sinonasal malignant neoplasms include:
 - Occupational exposure to wood dust is linked to the development of sinonasal adenocarcinomas, intestinal types, and to a lesser extent squamous cell carcinoma.
 - Occupational exposure to nickel refining and chromate pigment manufacture is linked to an increased risk of sinonasal carcinoma.
 - Epstein-Barr virus (EBV) present in association with some sinonasal tract neoplasms including:
 - NK/T-cell lymphoma
 - Lymphoepithelial-like carcinoma
 - Human papillomavirus (HPV), mainly high-risk types, may be present in association with some sinonasal tract neoplasms, including:
 - Schneiderian papilloma (include low- and high-risk HPV)
 - As many as 20% of sinonasal carcinomas may harbor transcriptionally active high-risk HPV:
 - Almost always nonkeratinizing squamous cell carcinoma (SCC)
 - Less commonly with other morphologic types including:
 - keratinizing SCC (de novo or in association with Schneiderian papilloma)
 - basaloid SCC
 - papillary SC
 - adenosquamous carcinoma
 - other morphologic types
 - Prognostic significance of transcriptionally active HPV in sinonasal SCC remains uncertain; unclear whether ameliorating prognostic effect as may occur in association with HPV-associated carcinomas of oropharynx also applicable to HPV-associated sinonasal carcinomas
- Premalignant lesions:
 - Unlike other upper aerodigestive tract sites, in particular the oral cavity and larynx, isolated premalignant lesions of the sinonasal tract (i.e., high-grade intraepithelial dysplasia and carcinoma in situ) are rarely seen unless associated with another neoplasm:
 - Often seen in association with an invasive squamous cell carcinoma, including conventional keratinizing type, nonkeratinizing carcinoma, basaloid squamous cell carcinoma, others
 - May be seen in association with a carcinoma arising in association with a benign neoplasm (e.g., malignant transformation of Schneiderian papilloma)
 - Although an extremely rare occurrence, sinonasal high-grade intraepithelial dysplasia can be seen in association with non-neoplastic sinonasal tract lesions, such as inflammatory polyps.
 - Squamous cell carcinoma and variants thereof may develop from inverted and oncocytic types of Schneiderian papillomas:
 - HPV can be found in these types of Schneiderian papillomas, but there is no definitive link between the presence of HPV and the development of sinonasal squamous cell carcinoma.
 - No known association between the presence of squamous metaplasia of the sinonasal epithelium and the development of squamous cell carcinoma
- Cytogenetics and molecular genetics:
 - For the majority of patients with head and neck squamous cell carcinoma and its variants, there are genetic alterations at the short arm of chromosome 9 regions.
 - Specific types of squamous cell carcinoma demonstrate distinctive molecular alterations.
 - These findings support the early involvement of these chromosomal loci in squamous epithelial carcinogenesis and support their temporal occurrence prior to the phenotypic diversion.
- Not infrequently, sinonasal neoplasms are removed in pieces lacking orientation.
- Partial maxillectomy:
 - Usually performed for tumors situated in the inferior portion of the maxilla (e.g., hard palate and alveolar recess)
 - The specimen includes a portion of the maxilla that may include the alveolar process, palate, and nasal turbinates.
 - For certain tumor types the incision may be extended to include the ethmoid complex and lateral nose.
- Radical maxillectomy includes:
 - The entire maxillary wall, ethmoid labyrinth, with or without the orbital content
 - Anterior portion: anterior maxilla, anterolateral portion of the zygomatic process of the frontal bone, frontal processes of the maxilla, medial and inferior walls of the orbit:
 - Skin and soft tissue overlying the anterior maxilla may be removed.

- Posterior margin: pterygoid muscle
 - If the orbit is resected, then the optic nerve and orbital content are the posterior margin.
- Medial margin: transected hard palate and maxilla
- Lateral margin: zygomatic arch
- Superior margin:
 - If orbit removed, exposed orbital soft tissue
 - If orbit not removed, floor of orbit

TNM Classification for Sinonasal Tract Neoplasms (Table 3-1)

Anatomic Site

- For staging purposes the sites of inclusion include:
 - Maxillary sinus
 - The nasoethmoid complex, which includes:
 - Nasal cavity
 - Ethmoid sinuses

Nasal Cavity

- The nasal cavity is subdivided into four subsites:
 - Septum
 - Floor
 - Lateral wall
 - Vestibule

Maxillary Sinus (Fig. 3-1)

- The maxillary sinus is divided into right and left.
- Ohngren line connecting the medial canthus of the eye to the angle of the mandible dividing the maxillary sinus into an anteroinferior portion (infrastructure) and superoposterior portion (suprastructure) structures (see Fig. 3-1):
 - Carcinomas of the infrastructure are associated with a good prognosis.
 - Carcinomas of the suprastructure are associated with a poor prognosis:
 - The poorer prognosis with carcinomas of the suprastructure reflects early access of these tumors to critical structures, including the eye, skull base, pterygoids, and infratemporal fossa.

TABLE 3-1 TNM Classification of Sinonasal Tract Neoplasms

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Maxillary Sinus	
T1	Tumor limited to maxillary sinus mucosa with no erosion or destruction of bone
T2	Tumor causing bone erosion or destruction, including extension into the hard palate and/or middle nasal meatus, except extension to posterior wall of maxillary sinus and pterygoid plates
T3	Tumor invades any of the following: bone of the posterior wall of the maxillary sinus, subcutaneous tissues, floor or medial wall of orbit, pterygoid fossa, ethmoid sinuses
T4a	Moderately advanced local disease Tumor invades the anterior orbital contents, skin of the cheek, pterygoid plates, infratemporal fossa, cribriform plate, sphenoid or frontal sinuses
T4b	Very advanced local disease Tumor invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than maxillary division of trigeminal nerve (V ₂), nasopharynx, or clivus
Nasal Cavity and Ethmoid Sinuses	
T1	Tumor restricted to any one subsite, with or without bony invasion
T2	Tumor invading two subsites in a single region or extending to involve an adjacent region within the nasoethmoidal complex, with or without bony invasion
T3	Tumor extends to invade the medial wall or floor of the orbit, maxillary sinus, palate, or cribriform plate
T4a	Moderately advanced local disease Tumor invades any of the following: anterior orbital contents, skin of the nose or cheek, minimal extension to anterior cranial fossa, pterygoid plates, sphenoid or ethmoid sinuses
T4b	Very advanced local disease Tumor invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than maxillary division of trigeminal nerve (V ₂), nasopharynx, or clivus

BENIGN NEOPLASMS

SCHNEIDERIAN PAPILLOMAS

(Table 3-2, Figs. 3-2 through 3-10)

Definition: Group of benign neoplasms arising from the sinonasal (Schneiderian) mucosa and composed of a squamous or columnar epithelial proliferation with associated mucous cells.

Synonym: Sinonasal-type papillomas

Clinical

- Ectodermally derived lining of the sinonasal tract, termed the Schneiderian membrane, may give rise to three morphologically distinct benign papillomas

collectively referred to as Schneiderian or sinonasal-type papillomas. The three morphologic types are:

- Inverted
- Oncocytic (cylindric or columnar cell)
- Exophytic (fungiform, septal) papillomas
- Collectively, Schneiderian papillomas represent less than 5% of all sinonasal tract tumors.
- As reported in the literature, among sinonasal-type papillomas, the exophytic (septal) papilloma is the most common type; however, practical experience indicates that the inverted type is the most common subtype; the oncocytic type is the least common.

**Fig. 3-1.**

A, Diagram of a coronal view of the sinonasal cavities. The lines divide the maxillary sinuses into three zones: suprastructure, mesostructure, and infrastructure. Tumors limited to and below the mesostructure usually can be resected by a partial or total maxillectomy without an orbital exenteration. Tumors involving the suprastructure may need an orbital exenteration to reduce the chance of tumor recurrence. **B**, Diagram of the lateral view of a skull with the Ohngren line drawn. Tumors anterior to this line tend to have a better prognosis. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 263, Fig. 4-19.)

- In general, the sinonasal-type papillomas occur over a wide age range but are rare in children:
 - Inverted papillomas are most common in the fifth to eighth decades.
 - Oncocytic papillomas occur in a somewhat older age range (greater than 50 years) and are uncommon in patients younger than the fourth decade of life.
 - Exophytic (septal) papillomas tend to occur in a younger age group.
- Localization:
 - Exophytic papillomas almost invariably are limited to the nasal septum.
 - Inverted papillomas occur along the lateral nasal wall (middle turbinate or ethmoid recesses) with secondary extension into the paranasal sinuses (maxillary and ethmoid, and less often sphenoid and frontal); less frequently, inverted papillomas may originate in a paranasal sinus.
 - Oncocytic papillomas also are most often seen along the lateral nasal wall but may originate within a paranasal sinus (maxillary or ethmoid).
 - Inverted and oncocytic subtypes rarely occur on the nasal septum.
 - Inverted papillomas may occur in a paranasal sinus without involvement of the nasal cavity.
 - Schneiderian papillomas have a tendency to spread along the mucosa into adjacent areas.
 - Although uncommon, the sinonasal-type (Schneiderian) papillomas may originate in the

TABLE 3-2 Sinonasal (Schneiderian) Papillomas: Clinicopathologic Features

	Exophytic	Inverted	Oncocytic
Percentage	18% to 50%	47% to 79%	3% to 8%
Gender/Age	M > F; 20-50 yrs	M > F; 40-70 yrs	M = F; >50 yrs
Location	Nasal septum	Lateral nasal wall in region of middle turbinates with extension into sinuses (maxillary or ethmoid)	Lateral nasal wall and sinuses (maxillary or ethmoid)
Focality	Unilateral	Typically unilateral; rarely, bilateral (up to 10%); bilateral disease should prompt possibility of septal perforation from unilateral disease	Unilateral
Histology	Papillary fronds composed of a predominantly squamous (epidermoid) epithelium; mucocytes (goblet cells) and intraepithelial mucous cysts are present; delicate fibrovascular cores	Endophytic or “inverted” growth consisting of thickened squamous epithelium composed of squamous, transitional, and columnar cells (all three may be present in a given lesion) with admixed mucocytes (goblet cells) and intraepithelial mucous cysts; mixed chronic inflammatory cell infiltrate characteristically is seen within all layers of the surface epithelium	Multilayered epithelial proliferation composed of columnar cells with abundant eosinophilic and granular cytoplasm; outer surface of the epithelial proliferation may demonstrate cilia; intraepithelial mucous cysts, often containing polymorphonuclear leukocytes
Incidence of human papillomavirus	Approximately 50% positive; HPV 6 and 11 most common; rarely HPV 16 and 57b	Approximately 38% positive; HPV 6 and 11; less frequently HPV 16, 18; rarely HPV 57	Typically absent
Treatment	Complete surgical excision	Complete surgical excision; may require lateral rhinotomy or medial maxillectomy with en bloc excision	Complete surgical excision; may require lateral rhinotomy or medial maxillectomy with en bloc excision
Prognosis	Good following complete surgical excision; will recur if incompletely resected	Good following complete surgical excision; will recur if incompletely resected	Good following complete surgical excision; will recur if incompletely resected
Incidence malignant transformation	Rare	Approximately 10% (range reported of 2% to 27%); most commonly SCC and NKSCC; less common types including VC, MEC, SCSC, adenocarcinoma; synchronous (61%) > metachronous (39%)	4% to 17%; most commonly SCC; less common types include MEC, SCUNC, SNUC

HPV, Human papillomavirus; MEC, mucoepidermoid carcinoma; NKSCC, nonkeratinizing squamous cell carcinoma; SCC, (keratinizing) squamous cell carcinoma; SCSC, spindle cell squamous carcinoma; SCUNC, small cell undifferentiated neuroendocrine carcinoma; SNUC, sinonasal undifferentiated carcinoma; VC, verrucous carcinoma.

nonsinonasal tract sites, including the nasopharynx or the ear:

- Typically in such situations there is no connection to the sinonasal tract and/or to a Schneiderian papilloma extending from the sinonasal tract to these locations.
- In all likelihood such Schneiderian-type papillomas occurring in nonsinonasal tract sites arise from misplaced ectodermal-derived epithelial rests from the sinonasal tract.
- Typically, Schneiderian papillomas are unilateral; bilateral papillomas, in particular the inverted subtype, may occur with reported incidence of up to 10%:
 - In the presence of bilaterality, clinical evaluation to exclude the possibility of extension from unilateral disease (i.e., septal perforation) should be undertaken.
- Symptoms vary according to site of occurrence and include airway obstruction, epistaxis, asymptomatic mass, and pain.
- Schneiderian papillomas may occur simultaneously with nasal inflammatory polyps or other lesion types including (but not limited to) sinonasal hamartomas.
- Radiology: appearance varies with extent of disease:
 - A soft tissue density is seen early in the disease.

Fig. 3-2. Schneiderian papilloma, inverted type.

Coronal (**A**) T1-weighted, fat-suppressed, contrast-enhanced MR image shows a nonhomogeneously enhancing right nasal cavity mass that extends into the right ethmoid complex and obstructs the right maxillary sinus. Axial (**B**) T2-weighted MR image on the same patient again shows the nonhomogeneous nature of the right polypoid nasal mass that obstructs the right antrum. A small retention cyst or polyp is in the floor of the left antrum. This patient had an inverted papilloma. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 260, Fig. 4-14.)

Fig. 3-3. Schneiderian papilloma, inverted type.

A, Endoscopic appearance of the lesion seen along the floor and lateral wall of the nasal cavity; the tumor appears as a sessile, tan-white mucosal lesion. **B**, Resection specimen showing the tumor arising along the surface (*top*) as a flat, tan-white thickened area with an endophytic or inverted growth into the submucosal compartment (*top right*).

Fig. 3-4. Schneiderian papilloma, inverted type.

A, Endophytic or “inverted” growth pattern consisting of thickened epithelial nests arising from the surface and growing down into the stroma; the surface epithelium has undergone squamous metaplasia, and the stroma is composed of a myxomatous to fibrous tissue with admixed chronic inflammatory cells. **B**, Slightly higher magnification showing the endophytic pattern of growth of benign nonkeratinizing squamous epithelium. **C**, The epithelial proliferation is noteworthy for uniformity of nuclei maintaining consistency in polarity, absence of cytologic atypia, scattered mucous cysts, and the presence of neutrophils throughout the epithelium. **D**, Scattered intraepithelial mucocytes are present and assist in defining the papilloma as being of Schneiderian (mucosal) origin and not a squamous papilloma of cutaneous origin, which lacks intraepithelial mucocytes. **E**, Schneiderian papilloma, inverted type with “early” changes including epithelial proliferation with expansion and downward projection.

**Fig. 3-5. Schneiderian papilloma, exophytic (septal) type.**

This lesion on the septum is an exophytic, tan-white lesion with a cauliflower-like appearance.

- Opacification and mucosal thickening are present with more extensive disease.
- Evidence of pressure erosion of bone may be seen.
- Human papillomavirus (HPV) types 6/11, less often 16, and rarely other HPV types (e.g., HPV57), have been found in septal and inverted papillomas by various molecular biologic analyses (in situ hybridization and/or polymerase chain reaction):
 - Strong association identified between HPV and exophytic papillomas
 - Association between HPV and inverted papillomas less well defined:
 - Approximately 38% of inverted papillomas reported to be positive for HPV by molecular biologic evaluation

- To date, molecular biologic analysis of oncogenic papillomas has not identified the presence of HPV.
- Whether there is a cause and effect between the presence of HPV and the development of Schneiderian papillomas remains to be determined.
- p16(INK4a) not considered a useful surrogate marker for HPV detection across the various types of Schneiderian papillomas.
- HPV detection rates increase in inverted papillomas with epithelial dysplasia and malignant transformation (i.e., carcinoma) of inverted papillomas:
 - Increasing ratio of high-risk to low-risk HR HPV types as compared with “conventional” inverted papillomas (i.e., without dysplastic epithelium)
- Epstein-Barr virus has not been found to be associated with Schneiderian papillomas.

Pathology

Schneiderian Papilloma, Inverted Type

Gross

- Large, bulky, translucent masses with a red to gray color, varying from firm to friable in consistency

Histology

- Endophytic or “inverted” growth pattern consisting of markedly thickened squamous epithelial proliferation growing downward into the underlying stroma:
 - Exophytic growth, in addition to endophytic growth, may be present.
- Epithelium varies in cellularity and is composed of squamous, transitional, and columnar cells (all three may be present in a given lesion) with admixed mucocytes (goblet cells) and intraepithelial mucous cysts.
- Cells are generally bland in appearance with uniform nuclei and no piling up; however, pleomorphism and cytologic atypia may be present.
- Mixed chronic inflammatory cell infiltrate characteristically is seen within all layers of the surface epithelium.

Fig. 3-6. Schneiderian papilloma, exophytic (septal) type.

A, The tumor has a papillary growth protruding from the surface respiratory epithelium and composed of a thickened nonkeratinized squamous (epidermoid) epithelium. **B,** At higher magnification the epithelium shows cytomorphic uniformity, retention of cellular polarity, absence of cytologic atypia, presence of scattered mucous cysts, and intraepithelial inflammatory cells. **C,** Scattered intraepithelial mucocytes are present and assist in defining the papilloma as being of Schneiderian (mucosal) origin and not a squamous papilloma of cutaneous origin, which lacks intraepithelial mucocytes.

- Epithelial component may demonstrate extensive clear cell features indicative of abundant glycogen content (diastase-sensitive, PAS-positive).
- Mitotic figures may be seen in the basal and parabasal layers, but atypical mitotic figures are not seen.
- Surface keratinization may be present.
- Stromal component varies from myxoid to fibrous with admixed chronic inflammatory cells and variable vascularity.
- Histochemistry:
 - Intraepithelial mucocytes show intracytoplasmic mucin-positive material (mucicarmin-positive; diastase-resistant, PAS-positive).

Differential Diagnosis

- Sinonasal inflammatory polyps
- Nonkeratinizing respiratory (“transitional”) carcinoma
- Verrucous carcinoma

Schneiderian Papilloma, Exophytic (Septal) Type

Gross

- Septal papillomas are papillary, exophytic, verrucoid lesions with a pink to tan appearance and a firm to rubbery consistency; they are often attached to the mucosa by a narrow or broad-based stalk.

Histology

- Papillary fronds are seen and are composed of a thick epithelium, which is predominantly squamous (epidermoid) and, less frequently, respiratory type.
- Surface keratinization is uncommon.
- Mucocytes (goblet cells) and intraepithelial mucous cysts are present.
- Stromal component is composed of delicate fibrovascular cores.

Fig. 3-7. Schneiderian papilloma, oncocytic type appearing as an intranasal dark red to brown mass.

- Histochemistry:
 - Intraepithelial mucocytes will show intracytoplasmic mucin positive material (mucicarmine positive; diastase-resistant, PAS-positive).

Differential Diagnosis

- Verruca vulgaris
- Squamous papilloma:
 - In contrast to all of the sinonasal-type papillomas, squamous papilloma of the nasal vestibule does not have mucocytes as a part of the neoplastic proliferation.

Schneiderian Papilloma, Oncocytic Type

Gross

- Oncocytic papillomas are dark red to brown, papillary, or polypoid lesions.

Histology

- Multilayered epithelial proliferation composed of columnar cells with abundant eosinophilic and granular cytoplasm
- Nuclei vary from vesicular to hyperchromatic; nucleoli are usually indistinct.
- Outer surface of the epithelial proliferation may demonstrate cilia.
- Intraepithelial mucin cysts, often containing polymorphonuclear leukocytes are seen; cysts are not identified in the submucosa.
- Stromal component varies from myxoid to fibrous with admixed chronic inflammatory cells and variable vascularity.

Fig. 3-8. Schneiderian papilloma, oncocytic type.

A, Histologically this lesion is characterized by a multilayered papillary epithelial proliferation with multiple intraepithelial mucin cysts; cysts are not identified in the submucosal compartment. **B**, The cells consist of an eosinophilic to granular cytoplasm (oncocytes) with uniform, round nuclei and intraepithelial mucin cysts containing amorphous pink material and/or neutrophils; cilia can be seen at the outer surface of the epithelial proliferation.

- Histochemistry:
 - Intraepithelial mucocytes will show intracytoplasmic mucin-positive material (mucicarmine-positive; diastase-resistant, PAS-positive).

Differential Diagnosis

- Rhinosporidiosis
- Low-grade papillary adenocarcinoma

Treatment and Prognosis (for All Papilloma Types)

- Treatment for all sinonasal-type papillomas is complete surgical excision, including adjacent uninvolved mucosa; the latter is necessary because growth and extension along the mucosa results from the

Fig. 3-9. Schneiderian papilloma, inverted type.

A, Typically these tumors lack keratinization and when present, as seen in this illustration, some concern for the possibility of a coexisting squamous cell carcinoma or the development into a squamous cell carcinoma should be raised. **B**, Higher magnification shows the epithelium to be bland without evidence to suggest malignant transformation. **C**, In this example, more worrisome features of malignancy (i.e., squamous cell carcinoma) are present, including nests of tumor with cytologic atypia within the submucosa and **(D)** foci of severe dysplasia (carcinoma in situ). **E**, The patient did have a malignancy that was invasive, extending from one nasal cavity with destruction of the septum and extension to the other nasal cavity.

Fig. 3-10. Schneiderian papilloma, oncocytic type may also undergo malignant transformation.

A and **B**, Residual papilloma with oncocytic features are seen (top portion of images) with associated intraepithelial severe dysplasia and (**C**) areas of invasive growth. The carcinoma is nonkeratinizing, characterized by broad interconnecting cords of tumor, a pattern not typically seen in benign Schneiderian papillomas.

- induction of squamous metaplasia in the adjacent sinonasal mucosa:
 - Adequate surgery includes a lateral rhinotomy or medial maxillectomy with en bloc excision.
- Schneiderian papillomas of all histologic types will recur if incompletely resected; recurrence probably represents persistence of disease instead of multicentricity of the neoplasm.
- In general, prognosis is good following complete surgical excision; however, if left unchecked, these neoplasms have the capability of continued growth with extension along the mucosal surface with destruction of bone and invasion of vital structures (e.g., central nervous system, others).
- Adjuvant therapy (chemo- and radiotherapy) has not been demonstrated to be beneficial in sinonasal papilloma:
 - Radiation may prove beneficial in a select population of patients with unresectable tumors due to locally advanced disease.
- Complications associated with Schneiderian papillomas include recurrence and malignant transformation:
 - Inverted papillomas and oncocytic papillomas can undergo malignant transformation.
 - Incidence of malignant transformation varies per subtype:
 - Malignant transformation reported for the inverted subtype ranges from 2% to 27% but is more likely around 11%.
 - Malignant transformation reported for the oncocytic subtype ranges from 4% to 17%.
 - Malignant transformation relative to exophytic (septal) papilloma rarely, if ever, occurs.
 - Majority of the malignancies occurring in association with Schneiderian papillomas are squamous cell carcinomas (keratinizing and nonkeratinizing), varying in appearance from well to poorly differentiated; less frequently, other carcinomas may occur, including verrucous

carcinoma, mucoepidermoid carcinoma, spindle cell squamous carcinoma, small cell carcinoma, adenocarcinoma, and sinonasal undifferentiated carcinoma.

- Carcinoma may occur synchronously or metachronously with the papilloma:
 - Metachronous carcinomas develop with a mean interval of 63 months (range 6 months to 13 years) from the onset of the papilloma to the development of the carcinoma.
- Carcinomatous foci may be limited or extensive and may show epithelial dysplasia as well as carcinoma in situ or invasive carcinoma.
- Evidence of a pre-existing papilloma may be present with obvious transition from benign papilloma to overt carcinoma; other possibilities include a tumor that is predominantly benign (papilloma) with only limited foci of malignancy or a tumor that is predominantly a carcinoma with very limited residual papilloma.
- In some cases, there may be no residual evidence of a pre-existing benign tumor and only by history was the patient known to have had a previous benign sinonasal papilloma.
- There are no reliable histologic features that predict which papillomas are likely to become malignant:
 - Papillomas with increased cellularity, pleomorphism, and increased mitotic activity do not necessarily become malignant.
 - Presence of moderate to severe intraepithelial dysplasia is a potential indicator of malignant transformation.
 - Dysplastic epithelium will have increased p16, p53, and Ki67 expression.
 - Surface keratinization and dyskeratosis have anecdotally been considered as possible predictors of malignant transformation.
 - Any sinonasal papilloma that shows moderate to severe intraepithelial dysplasia or has surface keratinization should prompt thorough histologic examination of all resected tissue to exclude the presence of malignancy.
- There is no correlation between the number of recurrences and the development of carcinoma.
- Treatment for malignant transformation of a sinonasal papilloma includes surgery and radiotherapy.
- Prognosis for patients with malignant transformation varies:
 - In some patients the carcinomas are only locally invasive with favorable prognosis following treatment.
 - In other patients there may be extensive invasion with involvement of vital structures and/or metastatic disease; these patients generally have

a poor clinical outcome irrespective of therapeutic intervention.

SQUAMOUS PAPILLOMA OF THE NASAL VESTIBULE

Clinical

- Squamous papillomas represent the most common benign neoplasms of the upper aerodigestive tract mucosa and are commonly seen in the oral cavity and larynx; less often, squamous papillomas occur in the nasopharynx and nasal vestibule.
- For a more complete discussion on squamous papillomas see Section 2, Oral Cavity, and Section 5, Larynx.
- Nasal vestibular squamous papillomas are of cutaneous origin.
- In contrast to the sinonasal-type papillomas, squamous papillomas of the nasopharynx are endodermally derived.
- Squamous papillomas are exophytic, warty, or cauliflower-like tumors ranging in size from a few millimeters up to 3.0 cm in greatest dimension.
- Histologically, these tumors are composed of benign squamous epithelium arranged in multiple finger-like projections with prominent fibrovascular cores.
- In contrast to the sinonasal-type papillomas, cutaneous squamous papillomas lack intraepithelial mucocytes.
- In squamous papillomas the squamous epithelium is free of dysplastic change.
- In general, these tumors lack surface keratin, but in any tumor there may be (hyper)keratosis, as well as para- and orthokeratosis:
 - Presence of surface keratin carries no additional risk for the development of carcinoma.
- Surgical excision is the treatment of choice and is curative.
- Recurrences occur infrequently and relate to inadequate excision.
- Malignant transformation does not occur.

BENIGN MINOR SALIVARY GLAND NEOPLASMS

- Benign salivary gland tumors of the sinonasal region are uncommon.
- For a more complete discussion on benign salivary gland tumors see Section 6, Salivary Glands.
- In general, minor salivary gland tumors occur most often in the nasal cavity and rarely in the paranasal sinuses.

- Pleomorphic adenoma is the dominant histologic type seen; less often, monomorphic adenomas such as myoepithelioma and oncocytoma occur:
 - Pleomorphic adenomas of the sinonasal tract may be hypercellular, dominated by the presence of epithelial cells or myoepithelial cells or both cellular components.
 - Not infrequently, such neoplasms are myoepithelial-predominant pleomorphic adenomas.
 - There may be a limited amount of chondromyxoid stroma.
- Pleomorphic adenomas tend to originate along the nasal septum (bony or cartilaginous component) more than any other site.
- Although these tumors may arise from within the paranasal sinus, more often paranasal sinus involvement occurs secondary to extension from an intranasal lesion.
- These tumors appear as polypoid or exophytic growths, usually covered by an intact mucosa, and vary in size from 1 to 7 cm.
- As is true of all upper aerodigestive tract minor salivary gland tumors (benign or malignant), the pleomorphic adenomas are unencapsulated; however, in contrast to malignant minor salivary gland tumors, these tumors are relatively circumscribed without invasive growth; involvement of surface epithelium does not constitute invasion:
 - Diagnostic caution should be exercised when confronted with biopsy material that essentially includes lesional tissue with limited to absent surrounding tissues; in such biopsy material, although lesional cells appear bland, lacking cytomorphic features of malignancy, there are histologic features shared by benign salivary gland neoplasms and malignant salivary gland neoplasms (e.g., growth patterns, cell types) such that differentiation may be predicated solely on the basis of the presence or absence of invasive growth.
 - In the above scenario, although the findings may suggest a diagnosis of a benign minor salivary gland neoplasm, a diagnosis of “minor salivary gland neoplasm, not further specified” or “minor salivary gland neoplasm, favor benign neoplasm” may be prudent, with the recommendation for conservative but complete surgical excision.
- Histologically, these tumors are identical to those of major salivary glands, including an admixture of ductular or tubular structures, spindle-shaped or plasmacytoid-appearing myoepithelial cells, and a chondromyxoid stroma.
- There is a tendency for pleomorphic adenomas of the nasal cavity to be cellular, showing a predominant myoepithelial component:
 - Myoepithelial cells usually are in the form of plasmacytoid (hyaline cell) rather than spindle-shaped myoepithelial cells.
 - Given the presence of ductular or tubular structures and chondromyxoid stroma, these tumors would not be considered as myoepitheliomas.
 - Myoepithelial differentiation can be shown by immunoreactivity for cytokeratins as well as p63, p40, calponin, S100 protein, smooth muscle actin, glial fibrillary acidic protein, and vimentin.
 - Rarely, skeletal muscle differentiation can be seen.
- Surgical excision is the preferred treatment for all types of benign minor salivary gland tumors.
- Surgery is usually curative, with local recurrence seen in less than 10% of patients.

LOBULAR CAPILLARY HEMANGIOMA (LCH)

(Figs. 3-11 and 3-12)

Definition: Benign polypoid form of capillary hemangioma occurring primarily on skin and mucous membranes.

Synonyms: Pyogenic granuloma; pregnancy tumor; epulis gravidarum. The term pyogenic granuloma is a misnomer in that this lesion is neither an infectious process nor granulomatous.

Clinical

- No gender predilection; wide age range commonly seen in the fourth and fifth decades of life but uncommon under 16 years of age

Fig. 3-11. Intranasal lobular capillary hemangioma characterized by a smooth lobulated, polypoid red mass.

Fig. 3-12. Intranasal lobular capillary hemangioma.

A, The lesion is submucosal and composed of cellular lobules consisting of dilated, irregularly shaped vascular spaces and surrounded by a cellular proliferation. **B** and **C,** The blood vessels may ramify with a “staghorn” appearance, but there is no intercommunicating of the vascular channels; the vessels are lined by flattened endothelial cells and are surrounded by granulation tissue with a chronic inflammatory cell infiltrate. The lobular pattern and admixture of cell types contrasts to sinonasal glomangiopericytoma, which is characterized by a diffuse growth composed of single cell type. **D,** Increased mitotic figures may be present (*arrows*) and have been referred to as “active” lobular capillary hemangiomas. This finding does not portend adverse behavior to the lesion.

- Most often identified in the anterior portion of the nasal septum referred to as Little’s area or Kisselbach’s triangle; next most common sinonasal location is the tip of the turbinates.
- Hemangiomas of the sinonasal tract tend to be mucosally based but also may arise from within the osseous components of this region (intraosseous hemangiomas).
- Aside from the lobular capillary hemangioma, other types of hemangiomas of the sinonasal cavity and nasopharynx are rare.
- Most common clinical complaint is epistaxis; an obstructive painless mass may be present.
- Pathogenesis remains unclear:
 - A minority of cases may be associated with prior trauma.
 - LCH may occur in association with pregnancy and in association with oral contraceptive use, suggesting that hormonal factors may be involved.
 - A hormonal role is further supported by the regression of these tumors following parturition; however, immunohistochemical evaluation failed to identify estrogen or progesterone receptors in any of these tumors.
 - The mechanism for the regression of pregnancy-related pyogenic granuloma after parturition remains unclear; proposed mechanisms for regression include the absence of vascular endothelial growth factor (VEGF) and angiopoietin-2 (Ang-2), causing blood vessels to regress:
 - Amount of VEGF has been found to be high in the LCH in pregnancy and almost undetectable after parturition, suggesting that a lack of

VEGF is associated with apoptosis of endothelial cells and regression of these tumors.

- No role for Ang-2 alone in regression has been found.

Pathology

Gross

- Smooth, lobulated, polypoid red mass measuring up to 1.5 cm in diameter

Histology

- Characterized by a submucosal vascular proliferation arranged in lobules or clusters composed of central capillaries and smaller ramifying tributaries:
 - Central capillaries vary in caliber, as well as in shape, and in more “mature” lesions may show a “staghorn” appearance.
- Endothelial cell lining may be prominent and may display endothelial tufting, as well as mitoses, but atypical mitoses are not identified:
 - Designation of “active” LCH can be used in conjunction with those tumors showing an increase of mitotic activity, but these “active” lesions carry no additional risk of aggressive behavior or of transformation to an angiosarcoma.
- There is no intercommunication of vascular spaces as seen in angiosarcomas nor is there true cytologic atypia or atypical mitoses.
- Surrounding and intimately associated with the vascular component is granulation tissue and a mixed chronic inflammatory cell infiltrate.
- Surface epithelium is often ulcerated with associated (fibrinoid) necrosis but may show squamous metaplasia with or without hyperplastic changes.
- Immunohistochemistry:
 - Lesional cells are reactive for CD31, CD34, and Factor VIII-related antigen; androgen receptor (nuclear) reactivity may be present.
 - No immunoreactivity is present for glucose transporter 1 (GLUT1), human herpesvirus 8 (HHV-8).

Differential Diagnosis

- Sinonasal-type hemangiopericytoma-like tumor:
 - Diffuse growth pattern composed of a single cell type and presence of perivascular hyalinization contrast to the findings seen in LCH
- Angiofibroma
- Infantile hemangiomas:
 - GLUT1 positive
 - See Section 6, Salivary Gland for more detailed discussion.
- Angiosarcoma

Treatment and Prognosis

- Treatment includes conservative but complete surgical excision of the lesion.

- Prognosis following excision is excellent.
- Recurrences are relatively infrequent.

OTHER BENIGN VASCULAR TUMORS

- Cavernous hemangiomas occur less frequently in the upper respiratory tract when compared with the capillary hemangioma.
- In general, cavernous hemangiomas have a similar clinical presentation to capillary hemangiomas but are more often identified in the turbinates, lateral nasal wall, or within bone (intraosseous) than in the nasal septum.
- Similar to histology of cavernous hemangiomas of other sites, those of the sinonasal tract are composed of multiple, variably sized, dilated and thin-walled, endothelial cell-lined vascular spaces.
- Surgical resection is curative.

SINONASAL HEMANGIOPERICYTOMA-LIKE TUMOR (GLOMANGIOPERICYTOMA) (Figs. 3-13 through 3-15)

Definition: Sinonasal tumor showing perivascular myoid differentiation, typically with indolent biologic behavior.

Fig. 3-13. Sinonasal hemangiopericytoma-like tumor.

The resection specimen shows the tumor to be a glistening, red polypoid mass (lower right of the tissue specimen).

Fig. 3-14. Sinonasal hemangiopericytoma-like tumor.

A, The tumor characteristically is submucosal without involvement of the surface epithelium and is cellular, diffuse in its growth, and well vascularized; the vascular spaces toward the surface are readily apparent as compared with compressed vascular spaces within the depth of the lesion. **B,** The neoplastic cells are tightly packed with hyperchromatic nuclei and situated in and around endothelial-lined vascular spaces; the latter appear dilated and irregularly shaped, but there is no intercommunication of the vascular channels. **C,** A characteristic finding relative to the vascular spaces is the presence of perivascular (peritheliomatous) hyalinization that in conjunction with the cytomorphology assists in recognizing this tumor. **D,** The cells are uniform in size and shape and have round to oval nuclei with fine nuclear chromatin and an indistinct cytoplasm; perivascular hyalinization is present. **E,** In some tumors the cells are spindle-shaped; in this densely cellular tumor there is compression of vascular spaces, which appear slit-like instead of dilated and irregularly shaped; extravasation of erythrocytes is present. **F,** In any given tumor nuclear pleomorphism and scattered mitotic figures may be present, but usually marked pleomorphism, increased mitotic activity, necrosis, and invasive growth are not seen except for (multiply) recurrent tumors and/or in overtly malignant tumors.

Fig. 3-14, cont'd

G, Multinucleated giant cells may focally be present. **H**, An unusual feature may include a whorling pattern of growth. **I**, Reticulin stain shows envelopment of individual pericytes by the black staining reticulin fibers.

Synonyms: Sinonasal-type hemangiopericytoma; sinonasal glomus tumor

NOTES:

- The classification of this sinonasal tumor has evolved from its designation for the last several decades as sinonasal hemangiopericytoma-like tumor, reflecting the uncertainty of its relationship to soft tissue hemangiopericytoma, to the current designation of sinonasal glomangiopericytoma, reflecting a perivascular myoid differentiation.
- The current classification of soft tissue hemangiopericytoma incorporates it within the spectrum solitary fibrous tumor (SFT) based on the presence of *NAB2-STAT6* gene fusion and STAT6 immunoreactivity.
- Limited studies to date have shown that sinonasal hemangiopericytoma-like tumors are negative for *NAB2-STAT6* gene fusion and/or STAT6 immunoreactivity, precluding classification within the spectrum of SFT and soft tissue hemangiopericytoma.

- Genetic abnormalities seen in association with glomus tumor and pericytoma include *miR143-NOTCH* fusions and *GLI1*, respectively, but neither NOTCH or GLI reported in sinonasal hemangiopericytoma-like tumor.
- Based on the limited genetic studies reported in the literature to date, it would appear that the sinonasal hemangiopericytoma-like tumor does not merit classification within the spectrum of SFT/soft tissue hemangiopericytoma or glomangiopericytoma but perhaps does merit the retention of the designation sinonasal hemangiopericytoma-like tumor, although its eventual classification based on more defining molecular findings may yet to be determined.

Clinical

- Represents less than 1% of all sinonasal tract tumors
- No gender predilection; occurs over a wide age range but is most commonly seen in the sixth to seventh decades of life

Fig. 3-15. Immunohistochemical staining in sinonasal-type hemangiopericytoma.

Immunohistochemical staining of sinonasal hemangiopericytoma-like tumor includes **A**, vimentin; **B**, muscle specific actin; **C**, β -catenin (nuclear); and **D**, CD34, which occasionally can be identified and does not exclude this diagnosis in a lesion with typical light microscopic features and absence of STAT6 immunostaining, the latter present in solitary fibrous tumors.

- Typically presents as a unilateral nasal mass with obstruction and epistaxis; extension into adjacent paranasal sinuses may occur, but isolated involvement to a paranasal sinus is uncommon.
- Radiology:
 - Opacification of the involved sinus
 - Bone erosion due to pressure may be seen.
 - Arteriographic findings reveal a richly vascular neoplasm.
- There are no known etiologic factors.
- May rarely cause oncogenic osteomalacia (OO):
 - OO is a rare paraneoplastic syndrome of osteomalacia due to phosphate wasting.
 - Phosphaturic mesenchymal tumor (mixed connective tissue variant) extremely rare, distinctive tumor frequently associated with OO
 - Overexpression of fibroblast growth factor-23 (FGF-23), a phosphaturic hormone, shown in phosphaturic mesenchymal tumor

- Phosphaturic mesenchymal tumor is a soft tissue tumor histologically characterized by:
 - Hemangiopericytoma-like areas and osteoclast-like giant cells with or without osseous and cartilaginous metaplasia
 - "Grungy" calcified matrix identified

Pathology

Gross

- Red to tan-gray, soft to firm polypoid mass of varying size

Histology

- Submucosal, circumscribed, but unencapsulated cellular tumor with effacement of seromucous glands, although seromucous glands may be retained although surrounded by lesional cells.
- Diffuse growth pattern composed of single cell type situated around endothelial-lined vascular spaces

- Lesional cells are usually arrayed in short fascicles, and less often may show storiform, whorled, or even palisaded growth patterns with little intervening stromal collagen.
- Lesional cells are usually uniform with round to oval nuclei, vesicular to hyperchromatic-appearing chromatin, and indistinct eosinophilic cytoplasm; occasionally, spindle-shaped cells are seen.
- Mild nuclear pleomorphism and an occasional mitotic figures can be seen, but typically there is an absence of increased mitotic activity, atypical mitoses, and necrosis.
- Vascular channels range from capillary size to large sinusoidal spaces that may have a “staghorn” or “antler-like” configuration.
- A characteristic but not pathognomonic feature is the presence of perivascular hyalinization.
- Cellular proliferation may compress and obscure blood vessels of smaller size.
- Extravasated erythrocytes are often identified.
- An inflammatory cell component usually including mast cells but also eosinophils is present scattered throughout the tumor.
- Multinucleated (tumor) giant cells can be seen in a minority of cases.
- Fibrosis or a myxoid stroma may be seen, especially in tumors undergoing degenerative change.
- Heterologous metaplastic elements, including bone and cartilage, may occasionally be seen; lipomatous change may also be present.
- Histochemistry:
 - Reticulin stain reveals a distinctive pattern characterized by envelopment of individual pericytes by reticulin fibers.
- Immunohistochemistry:
 - Consistent immunoreactivity for vimentin and smooth muscle actin
 - Majority of cases stain for Factor XIIIa, muscle-specific actin, β -catenin (nuclear) and cyclin D1 (nuclear):
 - Nuclear expression of β -catenin and cyclin D1 represent sign of oncogenic activation and demonstrate that mutational activation of β -catenin and associated cyclin D1 overexpression may be central events in pathogenesis.
- Negative for STAT6
- Typically negative for CD34, but in any given case CD34 staining may be present.
- Variably reactivity for S100 protein
- Typically do not stain for cytokeratins, CD31, Factor VIII-related antigen, desmin, neuron-specific enolase, EMA, CD68, bcl-2, CD99, TLE1, Fli1, and CD117
- Electron microscopy:
 - Pericellular basal lamina, pinocytotic vesicles, intracytoplasmic (thin) filaments, dense bodies, and membranous attachment plaques
- Cytogenetics and molecular biology:
 - Absence of *NAB2-STAT6* gene fusion (this gene fusion reported in solitary fibrous tumors/soft tissue hemangiopericytoma)
 - Absence of *miR143-NOTCH* fusions (these gene fusions reported in glomus tumor)
 - Absence of *GLI1* (this gene fusion seen in reported in pericytoma)

Differential Diagnosis

- Lobular capillary hemangioma
- Nasopharyngeal angiofibroma
- Glomus tumor (glomangioma)
- Solitary fibrous tumor (SFT):
 - In contrast to the solitary fibrous tumor, sinonasal hemangiopericytoma-like tumor lacks the presence of “ropey” keloidal-appearing collagen or amianthoid fibers and bcl-2 staining.
 - Sinonasal hemangiopericytoma-like tumor and SFT may show the presence of CD34 immunoreactivity; however, the extent of CD34 immunoreactivity varies:
 - In sinonasal hemangiopericytoma-like tumor CD34 staining if present is localized and not diffuse.
 - In solitary fibrous tumors CD34 tends to be diffuse and strong.
 - STAT6 immunoreactivity seen in SFT but not in sinonasal hemangiopericytoma-like tumor
 - *NAB2-STAT6* gene fusion seen in SFT but not in sinonasal hemangiopericytoma-like tumor
- Smooth muscle tumors (leiomyoma and leiomyosarcoma)
- Benign and malignant fibrohistiocytic neoplasms
- Synovial sarcoma
- Mesenchymal chondrosarcoma

Treatment and Prognosis

- Surgery is the preferred treatment and should include complete excision to include tumor-free margins.
- Considered radioresistant neoplasms
- Indolent behavior with overall 5-year survival rates of greater than 90%
- Local recurrence may occur in as high of 30% of cases and is likely due to inadequate surgical excision:
 - Recurrence can be anticipated over extended follow-up periods (1 to 2 decades).
- Aggressively behaving sinonasal hemangiopericytoma-like tumors are uncommon and include tumors that are locally destructive or are metastatic.
- Findings potentially linked to aggressive behavior include:
 - Large tumor size (greater than 5 cm)
 - Marked nuclear pleomorphism
 - Increased mitotic activity

- Necrosis
- Invasive growth (e.g., bone)
- Proliferation index of greater than 10%
- Metastatic tumor is uncommon; if it occurs, spread usually is to regional lymph nodes and lung and is preceded by (one or more) recurrent tumor.

SINONASAL TRACT MENINGIOMA (Fig. 3-16)

- Meningiomas are benign neoplasms of meningothe-
lial cells representing from 13% to 18% of all intra-
cranial tumors; occurrence outside the central
nervous system is considered ectopic; ectopic menin-
giomas are divided into:
 - Primary ectopic meningiomas representing those
tumors with no identifiable central nervous
system connection
 - Secondary ectopic meningiomas representing those
tumors with central nervous system connection
- For a more complete discussion see Section 7, Ear
and Temporal Bone.
- Most common sites of occurrence of the ectopic
meningiomas of the head and neck region include
the middle ear and temporal bone and sinonasal
cavity; less commonly, oral cavity and parotid gland.
- Sinonasal tract meningiomas most often involve the
nasal cavity, or a combination of nasal cavity and
paranasal sinuses; less frequently, involvement may
be isolated to the nasopharynx, frontal sinus, or
sphenoid sinus.
- In the sinonasal cavity, symptoms include nasal
obstruction, epistaxis, headache, pain, visual distur-
bances, and facial deformity.
- Tumors may erode the bones of the sinuses with
involvement of surrounding soft tissues, the orbit,
and occasionally the base of the skull.
- Grossly, these tumors appear as a polypoid mass;
often, the tumor is curetted out and received as frag-
ments of solid, white tissue; a gritty consistency may
be noted.
- Among the histologic subtypes of meningioma, the
meningotheliomatous type is the most common in
the sinonasal cavity:
 - Histologic features include a lobular growth
pattern with tumor nests separated by a variable
amount of fibrous tissue.
 - Cells have a whorled arrangement and have
round to oval or spindle-shaped nuclei with pale-
staining cytoplasm and indistinct cell borders.
 - Characteristically, the nuclei have a punched-out
or empty appearance resulting from intranuclear
cytoplasmic inclusions.
 - Psammoma bodies, typical and numerous in
intracranial meningothe-
lial meningiomas, may be

seen but are not as common in the ectopically
located meningiomas.

- Immunohistochemistry:
 - Reactivity with epithelial membrane antigen
(EMA) and vimentin
 - Cytokeratins can be positive:
 - As a whole may be positive in 20% of cases
 - May approach 40% positivity in epithelial
variants
 - No immunoreactivity with neuroendocrine markers
(chromogranin and synaptophysin, others)
- Surgical removal is the preferred treatment:
 - Complete surgical excision may be difficult to
achieve, resulting in recurrence; recurrence rates
range up to 30%.
- Following the histologic diagnosis, it is essential to
exclude spread from a primary intracranial neoplasm.

ECTOPIC PITUITARY ADENOMA (EPA) (Fig. 3-17)

Definition: Pituitary adenoma that arises in upper
aerodigestive tract mucosal sites from remnants of
Rathke's pouch without any continuity/connection with
the sella turcica.

NOTE: Pituitary neoplasms originating from their
usual origin in the sella turcica may occasionally extend
into the sinonasal tract or nasopharynx and appear to
present as a primary neoplasm of those regions. There-
fore, prior to rendering a possible diagnosis of EPA,
radiographic analysis is required to exclude derivation
from the normally situated pituitary gland within the
sella turcica.

Clinical Features

- No gender predilection; occurs in adults
- Clinical presentation may include airway obstruc-
tion, chronic sinusitis, visual field defects, cere-
brospinal fluid leakage, and endocrinopathic
manifestations (e.g., Cushing's syndrome, hirsutism).
- Most common ectopic sites of occurrence are the
sphenoid sinus followed by the nasopharynx:
 - Other less common sites include the nasal cavity
and ethmoid sinus; rarely, may involve the clivus.

Pathology

Gross

- Polypoid appearance

Histology

- Submucosal epithelioid neoplastic proliferation with
solid, organoid, and trabecular growth patterns:
 - Epithelioid cells have round nuclei with a
dispersed nuclear chromatin pattern and granular
eosinophilic-appearing cytoplasm.

Fig. 3-16. Sinonasal meningioma.

A, Submucosal cellular proliferation with lobular growth pattern and tumor nests separated by a variable amount of fibrous tissue. **B**, At higher magnification the tumor nests have a whorled arrangement composed of cells with round to oval to spindle-shaped nuclei with pale-staining cytoplasm and indistinct cell borders; characteristically, the nuclei have a punched-out or empty appearance resulting from intranuclear cytoplasmic inclusions. **C**, Psammoma bodies as seen in this sinonasal meningioma tend to be less common in ectopically located meningiomas as compared to **D**, intracranial meningiomas; meningiomas are immunoreactive for **(E)** epithelial membrane antigen and **(F)** vimentin.

Fig. 3-17. Ectopic pituitary adenoma.

A, Submucosal neoplastic proliferation showing solid growth; additional growth patterns may include **(B)** trabecular; **(C)** ribbon-like; **(D and E)** uniform epithelioid cells with round nuclei and dispersed nuclear chromatin pattern; cells with granular eosinophilic-appearing cytoplasm and plasmacytoid-appearing cells are present. **F**, Extracellular hyalinization and calcifications, including psammoma body concretions, may be identified.

**Fig. 3-17, cont'd**

Immunoreactivity is present for **(G)** cytokeratin (focally with paranuclear punctuate staining), **(H)** chromogranin, as well as a variety of pituitary hormones, among the latter including **(I)** prolactin and **(J)** luteinizing hormone.

- Plasmacytoid-appearing cells may be present.
- Mild to moderate nuclear pleomorphism may be identified.
- Scattered mitotic figures may be present but atypical mitoses are not identified; necrosis is absent.
- Gland-like spaces may be seen; absence of squamous differentiation
- Calcifications and/or psammoma-like concretions may be identified.
- Infiltrative growth can be identified, including in and around residual seromucous glands as well as into bone.
- Immunohistochemistry:
 - Cytokeratin (AE1/AE3, CAM5.2, others) positive:
 - Tends to be diffuse and strong, and show paranuclear dot-like pattern
 - Neuroendocrine markers positive, including:
 - Chromogranin, synaptophysin, CD56, neuron-specific enolase
 - Vimentin and S100 protein positive:
 - S100 protein lacks peripheral sustentacular staining pattern seen in paragangliomas and olfactory neuroblastoma
 - Pituitary hormones, including growth hormone, adrenocorticotrophic hormone (ACTH), prolactin, thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH):
 - Reactivity with two or more hormones, so-called plurihormonal pituitary adenoma, may be seen in up to approximately 50% of cases.
 - Approximately one third of cases express a single hormone:
 - Prolactin most common
 - In up to approximately 20% reactivity with pituitary hormone markers may be absent:
 - Referred to as null cell pituitary adenoma.

TABLE 3-3 Ectopic Pituitary Adenoma (EPA), Olfactory Neuroblastoma (ONB), Carcinoid and Paraganglioma: Comparison of Sites of Occurrence and Immunohistochemical Findings

	EPA	ONB	Carcinoid	Paraganglioma
Location	Sphenoid sinus » nasopharynx	Roof of nasal cavity	Uncommon in H&N; rarely occurs in SNT	Neck, ME; rarely if ever identified in SNT
Cytokeratins	Positive, diffuse/strong	Negative in majority of cases; may be positive in scattered lesional cells	Positive, diffuse/strong	Negative
NE markers	Positive	Positive	Positive	Positive
S100	Positive in lesional cells but not at periphery of lobules	Positive at periphery of lobules as well as in lesional cells	Positive in lesional cells but not at periphery of lobules	Positive at periphery of lobules
Pituitary markers	Positive in majority of cases; may be negative	Negative	Negative	Negative
Calretinin	Negative	Positive	Negative	Negative
Ki67	Low	Low: grades* 1, 2 High: grades* 3, 4	Low	Low

H&N, Head and neck; ME, middle ear; SNT, sinonasal tract.

Cytokeratins—AE1/AE3, CAM5.2, OSCAR; NE markers—neuroendocrine markers including synaptophysin, chromogranin, CD56.

*Refers to histologic grades.

- Low proliferation rates (less than 5%) by Ki67 (MIB1) staining
- Calretinin negative
- p53 negative

- Although benign, EPAs may be large and infiltrative, including into bone precluding surgical extirpation; in such cases radiation therapy can be used.
- Rarely, malignant transformation may occur.

Differential Diagnosis (Table 3-3)

- Paraganglioma
 - Rarely if ever occurs in the sinonasal tract
- Olfactory neuroblastoma (ONB)
 - ONBs predominantly arise in the superior aspect of the nasal cavity and rarely originate from the sphenoid sinus, the most common location for EPA.
 - Presence of diffuse and intense cytokeratin staining as seen in EPA essentially excludes a diagnosis of ONB, which is typically cytokeratin negative or at most only focally positive.
- Neuroendocrine carcinoma (e.g., carcinoid tumor):
 - Carcinoid tumor (well-differentiated neuroendocrine carcinoma) is so uncommon in the sinonasal tract as to be considered nonexistent.
- Malignant epithelial neoplasms (e.g., SNUC, other)

Treatment and Prognosis

- Wide surgical resection is the preferred treatment:
 - Complete removal may prove curative without recurrent or progressive tumor, and with resolution of endocrinopathic effects associated with the tumor.
 - Recurrence not uncommon especially for large tumors and/or incompletely excised tumors
- Medical therapy, bromocriptine (dopamine agonist) may be employed to control endocrinopathic effects of the tumor.

SOLITARY FIBROUS TUMOR (SFT), EXTRAPLEURAL (Fig. 3-18)

Definition: Solitary fibrous tumor (SFT) is a distinctive neoplasm composed of CD34-positive fibroblasts with hemangiopericytoma-like vascular pattern that are typically a (pleural) serosal-based proliferation but may occur in extrapleural sites.

NOTE: Current soft tissue classification of tumors links solitary fibrous tumor and hemangiopericytoma.

Clinical

- SFTs are rare but do occur in the upper aerodigestive tract, primarily involving the nasal cavity and paranasal sinuses.
- Patients with tumors in these sites present with nasal obstruction:
 - Usually, the symptoms have been present for an extended period of time (a year or more).

Pathology

- These tumors typically are polypoid.

Histology

- Unencapsulated tumor composed of a variably cellular proliferation of bland spindle-shaped cells lacking any pattern of growth and associated with

Fig. 3-18. Sinonasal solitary fibrous tumor.

A, Sinonasal unencapsulated tumor composed of a variably cellular proliferation of bland spindle-shaped cells lacking any pattern of growth with associated ropey collagen or **(B)** keloidal collagen bundles. **C**, The cells are immunoreactive for CD34 and **(D)** STAT6 (nuclear staining).

ropey, keloidal collagen bundles and associated thin-walled vascular spaces.

- Vascular spaces may be focally prominent and often have the branching appearance as seen in hemangiopericytomas.
- Rare mitoses may be seen, but the mitotic rate is not excessive; atypical mitoses are absent and necrosis is absent.
- Histologic variants include:
 - Lipomatous SFT:
 - Rare variant that consists of histologically benign SFT admixed with areas of mature fat
 - SFT with giant cells (giant cell angiofibroma):
 - Giant cell-rich form of SFT
- Immunohistochemistry:
 - Reactivity for CD34 (80% to 90%), CD99 (70%) and bcl-2 (30%), EMA (30%) and actin (20%):
 - CD34 reactivity tends to be diffuse and strong.
 - STAT6 immunoreactivity (nuclear)

- Absence of S100 protein, desmin, and cytokeratins

- Cytogenetics and molecular genetics:
 - Overexpression of *NAB2-STAT6* gene fusion:
 - Establish *NAB2-STAT6* as the defining driver mutation of SFT
 - Rearrangements of long arm of chromosome 12

Differential Diagnosis

- Sinonasal hemangiopericytoma-like tumor
- Smooth muscle tumors (leiomyoma)
- Peripheral nerve sheath tumors
- Fibrohistiocytic tumors
- Fibromatosis
- Nasopharyngeal angiofibroma

Treatment and Prognosis

- Given their tendency to be polypoid, solitary fibrous tumors of the sinonasal tract are amenable to complete surgical resection.

- Complete surgical resection is usually curative:
 - Recurrences generally a function of incomplete excision
 - SFTs of the nasopharynx may be more difficult to completely excise; despite incomplete resection, these tumors are not generally associated with adverse biologic behavior at this anatomic location.
 - Malignant transformation of SFT may occur in particular for intrathoracic or soft tissue but rarely for those of head and neck sites; histologic features associated with malignancy include:
 - Increased cellularity, pleomorphism, and increased mitotic activity ($>4/10$ high-power fields)
- BENIGN PERIPHERAL NERVE SHEATH TUMORS (BENIGN SCHWANNOMA AND NEUROFIBROMA) (Fig. 3-19)**
- This category of tumors includes benign schwannoma and neurofibroma.
 - For a more complete discussion of these tumor types see Section 2, Oral Cavity; 4, Neck; and 7, Ear and Temporal Bone.
 - Benign peripheral nerve sheath tumors of the head and neck are common, perhaps accounting for as many as 45% of all cases; benign peripheral nerve sheath tumors of the sinonasal tract (and nasopharynx) are uncommon, accounting for less than 4%.
 - In the sinonasal tract, schwannomas are substantially more common than neurofibromas.
 - Adults are most commonly affected, with no gender predilection.
 - Patients present with symptoms related to nasal obstruction and epistaxis:
 - Visual disturbances due to intracranial extension of the tumor may occur.
 - These tumors may cause pressure erosion of bone.
 - Nasopharyngeal involvement may result in unilateral serous otitis media.
 - There is no association with neurofibromatosis.

Fig. 3-19. Sinonasal benign peripheral nerve sheath tumor (benign schwannoma).

A, The tumor is submucosal, unencapsulated, and composed of a bland spindle-shaped cellular proliferation with associated blood vessels with perivascular hyalinization. **B,** Storiform growth of cells with spindle-shaped nuclei showing characteristic wavy or buckled appearance. **C,** At higher magnification the wavy nuclei can be seen as well as associated inflammatory cells and a blood vessel with perivascular hyalinization. **D,** Diffuse S100 protein immunoreactivity is present.

Benign Schwannoma

- Unlike their soft tissue counterparts, benign schwannomas of the upper aerodigestive tract are unencapsulated although circumscribed.
- Aside from the lack of encapsulation, the histologic features are similar to those described for benign peripheral nerve sheath tumors at other sites.
- These tumors are submucosal, show variable cellularity, including increased cellularity, but significant pleomorphism is not seen.
- Scattered mitotic figures may be present, but the mitotic rate is low and atypical mitoses are not present.
- Immunohistochemistry:
 - Diffuse and intense S100 protein and SOX10 immunoreactivity (cytoplasmic and nuclear pattern) are present.
 - Cytokeratins, actins, desmin, CD34, and epithelial membrane antigen staining are absent.
 - Low proliferation rate less than 5% is seen by Ki67 (MIB1) staining.

- Surgical resection is the preferred treatment and is curative.

Neurofibroma

- Submucosal, circumscribed tumors composed of spindle-shaped cells with “wavy” or buckled, hyperchromatic nuclei, and indistinct cytoplasm
- An associated collagenized and/or myxoid stromal component is present.
- Neoplastic cells are S100 protein (and SOX10) positive but extent of staining is less than that seen in schwannomas.
- Surgical resection is curative.

BENIGN FIBROUS HISTIOCYTOMA (Fig. 3-20)

Definition: Benign neoplasm composed of an admixture of fibroblasts and histiocytic cells.

Fig. 3-20. Sinonasal benign fibrous histiocytoma.

A, A submucosal densely cellular proliferation is present. **B** and **C**, The tumor has a fascicular to storiform growth pattern composed of an admixture of spindle-shaped cells (fibroblasts) and epithelioid cells (histiocytes), as well as scattered multinucleated giant cells and scattered chronic inflammatory cells. **D**, Benign fibrous histiocytomas may be cellular with mild cellular pleomorphism and scattered mitotic figures (*upper left*), but in the absence of other features (e.g., anaplasia, atypical mitoses, necrosis), these features are not indicative of malignancy.

Synonyms: Sclerosing hemangioma; cutaneous-derived are called dermatofibroma

Clinical

- Relatively uncommon neoplasm in the head and neck accounting for less than 5% of all fibrous histiocytomas
- More common in men than in women; occurs over a wide age range with a median age in the fifth decade of life
- Excluding cutaneous sites, the most common location in the head and neck is the nasal cavity and paranasal sinuses; other more common sites of occurrence include neck, larynx, and trachea.
- Symptoms vary according to site and include painless mass, nasal obstruction, epistaxis, pain, facial asymmetry, proptosis, loosening of teeth, hemoptysis, dyspnea, and stridor.

Pathology

Gross

- Polypoid or nodular, tan-white to yellow lesions varying in size

Histology

- Submucosal lesion composed of an admixture of spindle-shaped cells (fibroblasts) and epithelioid cells (histiocytes) in a fascicular or storiform growth pattern
- Multinucleated giant cells, an inflammatory cell infiltrate (lymphocytes, plasma cells, and eosinophils), and foam cells are seen scattered throughout the tumor.
- Stroma varies and may consist of collagen production, myxoid change, and hyalinization.
- Vascularity varies from relatively inconspicuous vessels to prominent vascular pattern with striking hyalinization.
- Pleomorphism and mitoses may be seen, but these features in excess or the presence of abnormal mitotic figures suggest malignancy.
- Histologic variants include:
 - Cellular fibrous histiocytoma:
 - Characterized by increased cellularity and more fascicular and less storiform growth pattern
 - Increased mitotic activity (mean 3 mitoses per 10 high-power fields) may be present.
 - Atypical fibrous histiocytoma:
 - Significantly greater nuclear atypia and mitotic activity in a lesion with background of classic fibrous histiocytoma
- Immunohistochemical staining reflects presence of multiple cell types including reactivity for:
 - CD68 (macrophages)
 - S100 protein (Langerhan cells)

- Vimentin
- Desmin may occasionally be reactive.
- No immunoreactivity for CD31, CD34, epithelial markers, endothelial cell markers
- Cellular fibrous histiocytomas commonly express smooth muscle actin.

Differential Diagnosis

- Nodular fasciitis
- Fibromatosis (see Section 4, Neck, for more complete discussion)
- Benign peripheral nerve sheath tumors (benign schwannoma, neurofibroma)
- Leiomyoma
- Solitary fibrous tumor
- Dermatofibrosarcoma protuberans (DFSP):
 - See Section 7, Ear and Temporal Bone, for a more complete discussion.
 - Most frequent on the trunk and extremities
 - Histologically, DFSP infiltrates the dermis and subcutis and in its central aspect is composed of plump fibroblasts arranged in a distinct storiform pattern; cellular pleomorphism is mild and variable mitotic activity is seen.
 - CD34 immunoreactive
 - Wide local excision is the preferred treatment.
- Undifferentiated pleomorphic sarcoma (formerly malignant fibrous histiocytoma)

Treatment and Prognosis

- Complete surgical excision is generally curative.

LEIOMYOMA

(Figs. 3-21 and 3-22)

Definition: Benign tumor of smooth muscle.

Fig. 3-21. Sinonasal leiomyoma characterized by a tan-white and whorled appearance.

Fig. 3-22. Sinonasal leiomyoma.

A, This spindle cell lesion was submucosal and shows a fascicular growth composed of interlacing cellular bundles and associated vascular spaces. **B**, The cellular component consists of cells with blunt-ended or "cigar-shaped" nuclei, abundant eosinophilic cytoplasm, and perinuclear vacuolization; no significant pleomorphism is present and there is absence of mitotic activity. **C**, Sinonasal (and other mucosal-based) leiomyomas may originate from smooth muscle cells of vascular walls as is seen in this illustration, with the neoplastic cells in direct continuity with the endothelial-lined blood vessel at the bottom; these tumors have been referred to as vascular leiomyomas. **D**, Masson trichrome stain highlights the cytoplasmic myofibrils.

Continued

Fig. 3-22, cont'd

E, Neoplastic cells are diffusely and intensely immunoreactive for smooth muscle actin.

Clinical

- In general, one of the least common mesenchymal tumors in the head and neck area owing to the relative absence of smooth muscle in this region:
 - Smooth muscle found in association with blood vessels or cutaneous appendages represents origin for many head and neck leiomyomas
 - Leiomyoma arising from blood vessels termed vascular leiomyoma
- More common in men than in women; may occur in all ages but generally is a tumor of adult life with a peak incidence in the sixth decade of life
- Most common sites of occurrence in the head and neck are:
 - Skin and oral cavity (lips, tongue, and palate)
 - Other sites that may be affected include the sinonasal tract and larynx.
- Within the sinonasal tract leiomyomas most often involve the turbinates.
- Usually presents as a painless mass and nasal obstruction; other symptoms include dysphagia, voice changes, and pain.

Pathology

Gross

- Solitary, well-demarcated, sessile, tan-white submucosal lesion usually measuring less than 3 cm in diameter but may attain larger sizes
- On cut section the tumor is homogeneous with a whorled appearance.

Histology

- Localized to the submucosa, appearing delineated, and characterized by the presence of interlacing

bundles or fascicles of cells composed of blunt-ended or “cigar-shaped” nuclei with abundant eosinophilic cytoplasm

- Nuclear palisading and perinuclear vacuolization may be seen, but there is no significant pleomorphism or mitotic activity; the nuclei may appear epithelioid.
- Neoplastic cells are seen in intimate association with vascular spaces (vascular leiomyoma).
- Degenerative type changes, including stromal fibrosis and mucinous or myxoid alterations, may be present.
- Hypercellular tumors, referred to as cellular leiomyoma, characterized by an absolute increase in cells, but lacking significant pleomorphism, mitotic activity, necrosis, or invasive growth may be identified.

Smooth Muscle Tumors of Uncertain Malignant Potential (SMTUMP)

- SMTUMP is histologically characterized by increased cellularity, moderate nuclear pleomorphism, and the presence of no more than four mitoses per 10 high-power fields.
- Locally, infiltrative growth (i.e., into bone) may occur in association with SMTUMP.
- Histochemistry:
 - Cytoplasmic myofibrils can be demonstrated by special stains appearing red with Masson trichrome and blue with phosphotungstic acid-hematoxylin (PTAH).
- Immunohistochemistry (for leiomyoma and SMTUMP):
 - Actin (smooth muscle and muscle-specific), vimentin, and desmin positive
 - S100 protein, CD34, CD31 negative
 - Proliferation rate for leiomyoma and SMTUMP as seen by Ki67 (MIB1) staining is low (less than or equal to 5%).
- Electron microscopy:
 - Myofilaments, pinocytotic vesicles, investing basal laminae

Differential Diagnosis

- Peripheral nerve sheath tumor (neurofibroma, schwannoma)
- Solitary fibrous tumor

Treatment and Prognosis

- Complete surgical excision is curative.
- Rarely recurs

RHABDOMYOMA

- Adult or fetal types of rhabdomyoma rarely occur in the sinonasal tract or nasopharynx.

- See Section 5, Larynx, for a more complete discussion.
- The cellular features of fetal rhabdomyomas show rhabdomyoblasts in different stages of differentiation, including spindle-shaped and strap cells; these findings may be worrisome for a diagnosis of rhabdomyosarcoma; however, in contrast to rhabdomyosarcoma, fetal rhabdomyomas tend to be circumscribed and lack nuclear atypia or mitotic activity.

OSSEOUS, FIBRO-OSSEOUS, AND CARTILAGINOUS TUMORS/LESIONS

Osteoma (Figs. 3-23 and 3-24)

Definition: Benign bone-forming tumors that are almost exclusively identified in the craniofacial skeleton.

- Controversy exists as to whether the osteoma represents a true neoplasm or possibly represents the end-stage of fibro-osseous lesion.

Clinical

- Sinonasal osteomas are more common in men and occur over a wide age range but are most often encountered in the second to fourth decades of life.
- These tumors are usually asymptomatic and are found only by radiographic studies.
- Symptoms associated with paranasal sinus osteomas include headaches, facial swelling or deformity, and ocular disturbances; meningitis secondary to cranial cavity extension and sinus or aural obstruction may occur.
- Most common sites of involvement are the paranasal sinuses with the frontal and ethmoid sinuses most often involved (frontal > ethmoid > maxillary > sphenoid); other sites of involvement include:
 - Temporal bone (osseous external auditory canal), skull, mandible, maxilla
- Radiology:
 - Sharply delineated radiopaque lesion confined to bone or protruding into a sinus
- Cause linked to trauma, infection (sinusitis), and development
- Sinonasal osteomas usually occur as a single lesion but may be associated with Gardner syndrome:
 - Autosomal dominant inheritance
 - Sentinel lesion for adenomatous polyposis coli (APC)
 - Characterized by intestinal (colorectal) polyposis, soft tissue lesions (fibromatosis, cutaneous epidermoid cysts, lipomas, leiomyomas), and multiple craniofacial osteomas

Fig. 3-23. Sinonasal osteoma.

Coronal (**A**) and axial (**B**) CT scans show an osteoma in the right frontal sinus. This osteoma arises from the roof of the sinus. Axial CT scan (**C**) on another patient shows a large left frontal sinus osteoma that obstructs the sinus. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia 2011, Elsevier, p 334, Fig. 4-164.)

Pathology

Histology

- Osteomas are well circumscribed and are composed of dense, mature, predominantly lamellar bone sometimes rimmed by osteoblasts.
- Interosseous spaces may be composed of fibrous, fibrovascular, or fatty tissue, and hematopoietic elements may be present.

Fig. 3-24. Sinonasal osteoma.

A, Submucosal proliferation composed of dense, mature predominantly lamellar bone associated with interosseous spaces composed of a loose fibrovascular stroma.

B, Portion of the osteoma composed of mature bony spicules associated with an interosseous fatty tissue component.

Differential Diagnosis

- Exostosis

Treatment and Prognosis

- Unless symptomatic, osteomas require no treatment.
- Symptomatic osteomas require complete surgical excision, which is curative.
- No known link to the development of osteosarcoma

Benign Fibro-osseous Lesions of Craniofacial Bones

- Category of histologically similar-appearing benign fibro-osseous lesions that include ossifying fibroma and fibrous dysplasia
- In the head and neck, occur most often in relation to gnathic (maxillary and mandibular) bones
- For a more complete discussion on ossifying fibroma and fibrous dysplasia see Section 2, Oral Cavity.
- Given its localization to the sinonasal tract, the psammomatoid ossifying fibroma is discussed here.
- See [Table 3-4](#) for a comparison of ossifying fibroma, psammomatoid ossifying fibroma, and fibrous dysplasia.

Psammomatoid (Active) Ossifying Fibroma (Figs. 3-25 and 3-26)

Definition: Variant of ossifying fibroma that typically occurs in the sinonasal tract and potentially may behave aggressively with locally invasive and destructive capabilities.

Synonyms: Cementifying or cemento-ossifying fibroma; juvenile active ossifying fibroma

Clinical

- No gender predilection; generally occurs in younger age groups (first and second decades) but can occur over a wide age range, including older individuals.
- Presenting symptoms include facial swelling, nasal obstruction, pain, sinusitis, headache, and proptosis.
- These lesions may occur in any area of the sinonasal tract but are most frequent in the ethmoid sinus and supraorbital frontal region (ethmoid > nasal cavity > maxillary sinus > frontal sinus); the orbit may also be involved.
- There may be involvement of a single site or multiple sinuses.
- Radiology:
 - Lytic or mixed lytic/radiopaque osseous and/or soft tissue mass varying from well-demarcated to invasive with bone erosion

TABLE 3-4 Benign Fibro-osseous Lesions: Clinicopathologic Comparison

	POF	OF	FD
Gender/age	F = M; younger age groups (first and second decades), but may occur in older individuals	F > M; third-fourth decades	F = M; first two decades of life
Location	Ethmoid sinus; supraorbital frontal region	No specific site of involvement	No specific site of involvement
Focality	Single site or involvement of multiple (contiguous) sites/sinuses	Single site	Monostotic (75%-80%); polyostotic (20%-25%)
Radiology	Lytic or mixed lytic/radiopaque osseous and/or soft tissue mass varying from well-demarcated to invasive with bone erosion	Well-circumscribed or sharply demarcated lesion with smooth contours	Poorly defined expansile osseous lesion with a thin intact cortex; predominantly fibrous lesions are radiolucent; predominantly osseous lesions are radiodense; lesions with an equal admixture of fibrous and osseous components have a ground-glass appearance
Histology	Bony spicules and distinctive mineralized or calcified "psammomatoid" bodies or ossicles admixed with a fibrous stroma; psammomatoid bodies vary from a few in number to a dense population of innumerable spheric bodies; osteoclasts are present within the ossicles, and osteoblasts can be seen along their peripheral aspects; the bony trabeculae vary in appearance and include odd shapes with a curvilinear pattern. The trabeculae are composed of lamellar bone with associated osteoclasts and osteoblastic rimming	Randomly distributed mature (lamellar) bone spicules rimmed by osteoblasts admixed with a fibrous stroma; central portions may be woven bone with lamellar bone at the periphery	Fibrous tissue component is nondescript and of variable cellularity; osseous component includes irregularly shaped trabeculae of osteoid and immature (woven) bone that is poorly oriented with misshapen bony trabeculae with odd geometric patterns including "C"-shaped or "S"-shaped configurations; the trabeculae typically lack osteoblastic rimming
Syndromes	No known association	No known association	Albright syndrome (1%-3%)
Treatment	Surgical resection	Surgical resection	Disease may stabilize at puberty and, in children, therapy should be delayed if possible until after puberty; surgical resection indicated in cases with compromise of function, progression of deformity, associated pathologic fracture(s), or the development of a malignancy
Prognosis	Good following complete excision; recurrence(s) often occur due to incomplete excision; may behave in an aggressive manner with local destruction and potential invasion into vital structures	Excellent	Good prognosis; recurrence rates are low and death due to extension into vital structures rarely occurs
Malignant transformation	Not known to occur	Not known to not occur	Malignant transformation (osteosarcoma) occurs in less than 1%

FD, Fibrous dysplasia; OF, ossifying fibroma; POF, psammomatoid ossifying fibroma.

Fig. 3-25.

Axial CT of psammomatoid active ossifying fibroma (PAOF) demonstrating an inhomogeneous, radiodense mass in the left ethmoid and maxillary sinuses causing bowing outward of the medial wall of the left orbit and displacement but not destruction of the nasal septum.

- Presenting symptoms include facial swelling, nasal obstruction, pain, sinusitis, headache, and proptosis.

Pathology

Histology

- The histology is that of a benign fibro-osseous proliferation composed of bony spicules and spherules admixed with a fibrous stroma.
- Most distinctive component is the presence of mineralized or calcified “psammomatoid” bodies or ossicles:
 - These ossicles vary from a few in number to a dense population of innumerable spheric bodies.
 - Ossicles are demarcated with a central blue to black appearance surrounded by a pink-appearing rim and with concentric laminations.
 - Ossicles vary from small with a round to oval shape to being larger and irregularly shaped and are present within the bony trabeculae as well as within the adjacent cellular stroma.
 - Osteoclasts are present within the ossicles, and osteoblasts can be seen along their peripheral aspects.
- Bony trabeculae vary in appearance and include odd shapes with a curvilinear pattern:
 - Trabeculae are composed of lamellar bone with associated osteoclasts and osteoblastic rimming.

- Transition zones between the spherical ossicles and bony trabeculae can be seen.
- Nonosseous component includes a cellular stroma with a fascicular to storiform growth composed of round to polyhedral to spindle-shaped cells with prominent basophilic nuclei and inapparent cytoplasmic borders:
 - Mitotic figures can be seen, but mitotic activity is not prominent and atypical mitoses are not present.
 - Cellular pleomorphism may be present, but anaplasia and necrosis are not identified.
- Giant cells can be seen among the psammomatoid ossicles or scattered throughout the nonosseous stromal component.
- Osteoid formation may be focally present.
- Trabecular (juvenile) ossifying fibroma:
 - Considered to be clinicopathologically distinct from psammomatoid ossifying fibroma
 - Less common than psammomatoid ossifying fibroma
 - Reported to occur in more narrow age range (2 to 12 years) and younger mean age (8.5 to 12 years) than psammomatoid ossifying fibroma (3 months to 72 years and 16 to 33 years)
 - Predominantly affects the jaws
 - Histologically composed of trabeculae of fibrillary osteoid and woven bone
 - Aggressive growth occurs in some—but not all—cases of both types.

Differential Diagnosis

- Fibrous dysplasia (see [Table 3-4](#))
- Ossifying fibroma (see [Table 3-4](#))
- Osteoblastoma
- Osteosarcoma
- Psammomatoid meningioma

Treatment and Prognosis

- Complete surgical excision is the preferred treatment.
- Prognosis is good following complete excision but, if margins are involved, recurrences often occur, and the tumors may behave in an aggressive manner with local destruction and potential invasion into vital structures.

Chondroma ([Fig. 3-27](#))

Definition: Benign neoplasm of cartilage.

Clinical

- Chondromas of the sinonasal tract and nasopharynx are rare.
- The most frequent sites of occurrence include the nasal septum and the nasopharynx.

Fig. 3-26. Psammomatoid active ossifying fibroma.

A and **B**, The lesions are characterized by the presence of numerous, small ovoid, calcified, or mineralized bony spicules with a psammomatoid appearance admixed and surrounded by a cellular (active) spindle cell component with hyperchromatic nuclei and indistinct cytoplasmic borders. **C** and **D**, Irregularly shaped bony spicules associated with spindle-shaped cells and myxomatous stroma; lighter-staining psammomatoid spherules that are present in association with the bony spicules and in the cellular stromal component may be seen focally, resulting in the production of cystic spaces.

Fig. 3-27. Nasal septal chondroma.

A, The cartilaginous tumor is situated below an intact squamous epithelium and clinically produced a polypoid, smooth-surfaced nodule. **B**, The chondrocytes are bland and lack features worrisome for a low-grade chondrosarcoma.

- Radiology:
 - Sinus opacification or a circumscribed radiolucent lesion can be seen by radiographic studies.
- Sinonasal chondromas appear as a polypoid, firm, smooth-surfaced nodule measuring usually from 0.5 to 2.0 cm and rarely greater than 3.0 cm.
- Histologically, these are lobulated tumors composed of chondrocytes recapitulating the normal histology of cartilage.
- Cellular pleomorphism, binucleate chondrocytes, or increased mitotic activity is not present.
- Conservative but complete surgical excision is the preferred treatment.
- Recurrences are uncommon.

SINONASAL MYXOMA AND FIBROMYXOMA

(Figs. 3-28 through 3-32)

Definition: Myxomas and fibromyxomas are benign neoplasms of uncertain histogenesis with a

Fig. 3-28. Sinonasal fibromyxoma.

Coronal T1-weighted (A), axial T1-weighted (B), and T2-weighted (C) MR images, axial CT scan (D), and reformatted sagittal (E) and coronal (F) CT scans show an expansile low signal intensity mass filling the right maxillary sinus. Minimal nonhomogeneity is seen in B. Very fine lace-like signal voids are seen in C. Entrapped high signal intensity secretions are present around the lesion. The CT scans show that within the lower portion of the mass there are thin, lace-like calcifications. This patient had a fibromyxoma. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, 2011, p 331, Fig. 4-160.)

Fig. 3-29. Sinonasal fibromyxoma.

The lesion is large, multinodular with a glistening tan-yellow appearance.

characteristic histologic appearance often behaving in an aggressive (infiltrating) manner. When a relatively greater amount of collagen is present, the term fibromyxoma (or myxofibroma) is used.

Clinical

- In the head and neck two forms of myxomas/fibromyxomas are identified:
 - Facial skeletal-derived
 - Soft tissue-derived

Facial Skeletal-Derived Myxoma

- No gender predilection; occurs over a wide age range but most frequently seen in the second and third decades of life
- In general, this is a tumor of the jaw bones and is uncommon in extragnathic locations:
 - The mandible (posterior and condylar regions) is affected more often than the maxilla (zygomatic process and alveolar bone).
 - Extragnathic tumors are uncommon and primarily involve the sinonasal tract; specifically, the maxillary sinus (antrum) is most often involved with secondary extension into the nasal cavity; extension to orbit and cranial cavity may occur.
- Presentation usually is as a painless swelling of the affected area.
- Radiology:
 - Unilocular or multilocular radiolucency with a “honeycomb” or “soap-bubble” appearance
 - May vary from being delineated or circumscribed to expansile and infiltrative

- Localization to the jaw bones has led to the belief that these tumors take origin from the primordial odontogenic mesenchyme or from an osteogenic embryonic connective tissue; in the sinonasal tract, these tumors appear to be of osseous derivation.

Myxoma of Soft Tissues

- Primarily a tumor involving the extremities
- No gender predilection; seen over a wide age range and is not specific to any decade of life
- In the head and neck, common sites include the paraoral soft tissues, pharynx, larynx, parotid gland, tonsil, and ear:
 - Myxomas of the ear are associated with Carney complex.
 - See Section 7, Ear and Temporal Bone, for a more detailed discussion.
- Presentation is that of an asymptomatic mass.
- Association between myxomas and fibrous dysplasia has been noted:
 - Referred to as Mazabraud syndrome
 - Multiple myxomas are present and tend to be intramuscular in localization.
 - Majority of patients have polyostotic type of fibrous dysplasia.
 - Patients also may suffer from McCune-Albright syndrome.
- Carney complex:
 - Syndrome of myxomas, spotty pigmentation, and endocrine overactivity
 - Autosomal dominant inheritance
 - Include cardiac myxomas, as well as myxomas of other sites (e.g., intraoral, ear)
 - Death due to cardiac myxoma may occur in up to 25% of patients with this complex.
 - Pigmented nodular adrenocortical hyperplasia, Cushing syndrome, and acromegaly also occur in this complex.

Pathology

Gross

- Delineated but unencapsulated multinodular, rubbery to firm, tan-yellow to gray-white lesion with a gelatinous appearance

Histology

- Histology is the same irrespective of the setting in which it occurs.
- These tumors show a scant, loosely cellular proliferation consisting of spindle-shaped or stellate-appearing cells embedded in an abundant mucinous stroma.
- Nuclei are small and hyperchromatic; cellular pleomorphism, mitotic figures, and necrosis are absent.
- The amount of collagenous fibrillary material varies between cases and, depending on the

Fig. 3-30. Sinonasal fibromyxoma.

A, The lesion is characterized by a lobular growth composed of spindle-shaped cellular proliferation associated with a mucinous stroma; compressed, slit-like vascular component can be identified. **B** and **C**, Loosely cellular proliferation consisting of spindle-shaped or stellate-appearing cells embedded in a fibrous or fibromyxomatous stroma.

extent, its presence may confer designation “fibromyxoma.”

- Periphery of the tumor appears circumscribed, but local infiltration with replacement of bone can be seen.
- A vascular component is present but is limited in extent:
 - Absence of the delicate plexiform capillary vascular network, a finding that can be seen in various sarcomas
- In intraoral location, odontogenic epithelium may or may not be seen.
- Mucinous stroma stains positively for acid mucopolysaccharides.
- Immunohistochemistry:
 - Vimentin positive
 - Negative for MUC4, β -catenin, CD34

Differential Diagnosis

- Sinonasal inflammatory polyps
- Dental papillae (for intraoral lesions)
- Vocal cord polyps (for laryngeal lesions)
- Peripheral nerve sheath tumors
- Low-grade fibromyxoid sarcoma
- Sarcomas with myxoid component (e.g., myxofibrosarcoma, liposarcoma, rhabdomyosarcoma, others)
- Cartilaginous tumors:
 - A separate and distinct benign tumor of cartilaginous origin that may involve the craniofacial and paranasal sinus bones is the chondromyxoid fibroma ([Fig. 3-33](#)):
 - More common in men than in women; most common in the second to third decades of life
 - Mandible is the most common site (symphysis or molar-retromolar area).

Fig. 3-31. Sinonasal myxoma.

Coronal CT scan (**A**) shows an expansile mass in the left anterior maxilla (*arrow*). The surrounding bone is intact. This patient had a myxoma. Axial T1-weighted (**B**), axial T2-weighted (**C**), and axial (**D**) and coronal (**E**) T1-weighted contrast-enhanced MR scans on a different patient show a large mass destroying part of the right maxillary alveolus and expanding and filling the left maxillary sinus, elevating and thinning the orbital floor. There is no infiltration of the orbit. The teeth roots are exposed by the tumor, and the tumor is fairly homogeneous in signal intensity. This patient had a myxoma. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 332, Fig. 4-162.)

- Symptoms include pain, loosening of the teeth, difficulties in opening the jaws, and headaches.
- Radiographic appearance varies, depending on the involved bone, from round or oval; well-demarcated, radiolucent lesion usually measuring less than 5 cm in long bones to large, irregularly outlined lesions in flat bones.
- Histology is characterized by a lobular appearance with lobules separated by vascularized connective tissue and a zonal arrangement of the cellular component: center of the lobules are predominantly myxoid with scattered stellate-appearing cells; periphery of the lobules are more cellular, composed of cells with round to oval to spindle-shaped nuclei, an

eosinophilic to amphophilic cytoplasm often with multipolar, stellate extensions

- FGF-23 expression reported in some cases of chondromyxoid fibroma (as well as aneurysmal bone cyst)
- With time, the myxoid areas may become fibrotic; presence of cartilage varies but never exceeds 75% of the total tumor volume;

Fig. 3-32.

Sinonasal myxoma with predominant myxoid stroma and a relatively hypocellular spindle-shaped cellular proliferation. A nondescript (compressed) identifiable vascular component is present, lacking the delicate plexiform capillary network often seen in association with various (myxoid) sarcomas.

osteoclastic giant cells and calcifications may be seen.

- Surgery (en bloc resection) is the preferred treatment; local recurrences may occur if incompletely excised (curettage); malignant transformation in the absence of prior irradiation rarely occurs.

Treatment and Prognosis

- Conservative but wide local excision is the preferred treatment.
- These tumors tend to be slow-growing and usually follow a benign course but may have the potential for local destruction following inadequate excision.
- Recurrence or metastasis does not occur:
 - Metastasis from a presumptive sinonasal myxoma or fibromyxoma should seriously place that diagnosis in doubt and probably represents a myxoid variant of a sarcoma (liposarcoma, myxofibrosarcoma, or rhabdomyosarcoma).

OSSIFYING (AND NONOSSIFYING) FIBROMYXOID TUMOR (OFMT) (Fig. 3-34)

Definition: Benign soft tissue tumor of uncertain differentiation.

NOTE: Although evidence suggests that this tumor is of peripheral nerve sheath origin (i.e., Schwannian differentiation), its definitive origin remains uncertain.

Fig. 3-33.

Chondromyxoid fibroma is characterized by **(A)** lobular appearance with lobules separated by vascularized connective tissue; the lobules demonstrate a zonal arrangement of the cellular component, with the center of the lobules being predominantly composed of a chondromyxoid matrix with scattered stellate-appearing cells and the periphery of the lobules being more cellular. **B,** Cellular components of the chondromyxoid fibroma include cells with round to oval spindle-shaped nuclei, an eosinophilic to amphophilic cytoplasm often with multipolar, stellate extensions set in a chondroid to mucinous-appearing matrix.

Fig. 3-34. Sinonasal ossifying fibromyxoid tumor.

A, This submucosal variably cellular proliferation was rimmed along its periphery by an incomplete shell of lamellar bone (top). **B** and **C**, Diffuse growth of neoplastic cells composed of uniform round to ovoid to spindle-shaped cells with small round to oval vesicular-appearing nuclei with indistinct eosinophilic cytoplasm set in collagenized or fibromyxoid stroma. **D**, S100 protein immunoreactivity is present but is less intense as compared with S100 protein staining of benign peripheral nerve sheath tumors.

Clinical

- In general an uncommon tumor, including in head and neck sites
- More common in men than in women; occurs over a wide age range but most often occurs in the fifth and sixth decades of life
- Most commonly is a soft tissue tumor of the upper and lower extremities:
 - Deep subcutis with attachment to underlying fascia and connective tissues (skeletal muscle, tendon)
 - Up to one third originate in muscle
 - May occur in the head and neck, including skin, sinonasal tract, oral cavity, pharynx, and neck

- In the sinonasal tract, symptoms may include nasal obstruction or a painless mass.
- Radiology:
 - Well-circumscribed mass with a peripherally situated incomplete ring of calcification
 - Intralesional calcifications may be present.
- No known cause but a number of cases reported following trauma/surgery to a given site

Pathology

Gross

- Well-circumscribed, lobulated, or multinodular lesions with a rubbery to firm consistency and a tan-white appearance; range in size from 1 to 7 cm in greatest dimension

Histology

- Well-circumscribed, lobular, or multinodular proliferation often with an incomplete peripheral shell of lamellar bone in or below a fibrous capsule:
 - The majority of cases (approximately 80%) show an incomplete peripheral shell of lamellar bone representing the ossifying variant.
 - Up to 20% may lack a bony shell, representing the nonossifying variant.
- Tumor lobules composed of uniform round, ovoid, or spindle-shaped cells with eccentrically located small round to oval vesicular-appearing nuclei with inconspicuous to small nucleoli and scant eosinophilic cytoplasm:
 - Cellularity is limited as is nuclear pleomorphism.
 - Scattered mitotic figures may be seen (one to two mitoses per 10 high-power fields).
- Growth patterns include diffuse or sheetlike, cords, nests, or randomly distributed.
- Stromal component may be myxoid, mucoid, hyalinized/collagenized or fibromyxoid; well-vascularized component that may include the presence of perivascular hyalinization:
 - Calcification and/or mature cartilage may rarely be seen.
 - Osteoid may infrequently be present.
- Atypical OFT has been applied for those tumors with increased cellularity, nuclear pleomorphism, and more than two mitoses per 10 high-power fields but without metastatic disease.
 - In the presence of metastasis the tumor is malignant (see below).
- Immunohistochemistry:
 - S100 protein, vimentin, and neurofibrillary protein (NFP) positive in the majority of cases:
 - S100 protein immunoreactivity tends to be less intense as compared with benign peripheral nerve sheath tumors.
- Desmin positive in approximately 40% of cases
- Variable reactive for GFAP, CD56, CD57, NSE, GFAP
- Occasionally may express cytokeratin, EMA, MUC5, smooth muscle actin
- Identification of collagen II production (suggests limited cartilaginous differentiation)
- Loss of SMARCB1/INI-1 (putative tumor suppressor gene located on chromosome 22q11.2 that encodes a protein that is expressed essentially in all nucleated cells) in majority of cases:
 - Loss of INI-1 or other genes on 22q is likely important in pathogenesis of these tumors.
- Expression of neuron-related markers, in addition to Schwann cell- and cartilage-associated markers, suggests a “scrambled” phenotype in OFMTs.

- Electron microscopy:
 - Abundant intracytoplasmic intermediate filaments with perinuclear whorl
 - External lamina, interdigitating cell processes, and ribosome-lamellar complexes may be identified.
- Cytogenetics and molecular genetics:
 - Recurrent rearrangements of the *PHF1* gene reported in OFMT, including typical, atypical, and malignant variants:
 - Supports importance of *PHF1* rearrangements in the pathogenesis of these lesions
 - Confirm relationship between typical and malignant OFMT
 - Suggests a role for *PHF1* fluorescent in situ hybridization (FISH) in the diagnosis of morphologically challenging cases

Differential Diagnosis

- Benign peripheral nerve sheath tumors:
 - “Conventional” and epithelioid variants
- Malignant peripheral nerve sheath tumors:
 - “Conventional” and epithelioid variants
- Solitary fibrous tumor
- Myxoid chondrosarcoma
- Epithelioid smooth muscle tumors

Treatment and Prognosis

- Complete surgical resection is the preferred treatment.
- Local recurrence may be seen in up to one third of cases and is likely due to incomplete surgical excision.
- Malignant OFMT:
 - Diagnosis predicated on the presence of metastatic disease
 - As compared with benign OFMTs, malignant OFMTs show increased cellularity, nuclear pleomorphism, increased mitotic activity (greater than two mitoses per 10 high-power fields), and increased osteoid.
 - However, cytologically bland tumors have rarely been reported to metastasize.
 - May show osteosarcomatous areas
 - Metastatic disease occurs primarily to lungs.

SINONASAL AMELOBLASTOMA (Figs. 3-35 and 3-36)

Definition: Ameloblastomas are locally aggressive (jaw) tumors with a high propensity for recurrence that are thought to arise from remnants of odontogenic epithelium, lining of odontogenic cysts, and the basal layer of the overlying oral mucosa.

Fig. 3-35. Sinonasal ameloblastoma.

Coronal CT scans (**A** and **B**) and coronal T2-weighted (**C**) and axial T1-weighted, fat-suppressed, contrast-enhanced (**D**) MR images show an expansile mass in the right maxillary sinus that has destroyed portions of the lower and lateral sinus walls. A bony fragment is seen within the mass that represents the elevated sinus floor. The right ethmoid sinuses are obstructed by the mass. This tumor has a high T2-weighted signal intensity and has enhanced nonhomogeneously. This patient had an ameloblastoma. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 385, Fig. 4-258.)

- See Section 2, Oral Cavity, for a more complete discussion of the more common gnathic ameloblastomas.
- Ameloblastomas of the sinonasal tract are uncommon but do occur and in particular involve the maxillary sinus:
 - Usually occurs by secondary extension from the maxilla
 - True primary sinonasal ameloblastomas without connection to gnathic sites uncommonly occur.
- Radiology:
 - In contrast to the characteristic multilocular and radiolucent presentation of ameloblastomas within the jaws, sinonasal ameloblastomas are described radiographically as solid masses or opacifications.
 - Bone destruction, erosion, and remodeling (remnant of bony shell delimiting the lesion as it grew) may be present.
- Suggested sources for the odontogenic epithelium include cell rests of the dental lamina, a developing enamel organ, the lining of an odontogenic cyst, basal cells of oral mucosa, or heterotopic embryonic organ epithelium.

Primary Sinonasal Ameloblastoma

- Decided male predilection; mean age at presentation of 59.7 years (approximately 15 to 25 years later than in patients with ameloblastoma occurring within the jaws)
- Patients usually present with a mass lesion and nasal obstruction; symptoms range from 1 month to several years in duration.
- Sites of involvement included the nasal cavity only, the paranasal sinuses only, or the nasal cavity and the paranasal sinuses.

Pathology Histology

- Similar in appearance to their gnathic counterparts and include unencapsulated proliferating nests, islands, or sheets of odontogenic epithelium resembling the enamel organ
- Epithelium is composed of:
 - Central area of loosely arranged cells similar to the stellate reticulum of the enamel organ

Fig. 3-36. Sinonasal ameloblastoma.

A, The tumor is composed of unencapsulated proliferating nests or islands of odontogenic epithelium. **B**, Ameloblastic epithelium includes a central area of loosely arranged cells similar to the stellate reticulum of the enamel organ and a peripheral area of palisading columnar or cuboidal cells with hyperchromatic small nuclei oriented away from the basement membrane (reverse polarity). **C**, Acanthomatous ameloblastoma. **D**, Granular cell ameloblastoma. **E**, Ameloblastomatous proliferation is arising in direct continuity with the intact sinonasal surface mucosal epithelium (top). This finding in the face of an isolated sinonasal mass without continuity with gnathic sites supports the histogenesis of these sinonasal tumors from totipotent cells of the sinonasal mucosal epithelium.

- Peripheral area of palisading columnar or cuboidal cells with hyperchromatic small nuclei oriented away from the basement membrane (so-called reverse polarity)
- Areas of hyalinization are often seen surrounding nests or follicles.
- Ameloblastomatous proliferation can be seen arising in direct continuity with the intact sinonasal surface mucosal epithelium, a finding that in conjunction with the absence of continuity with gnathic sites supports the histogenesis of these sinonasal tumors from totipotent cells of the sinonasal mucosal epithelium.
- Histologic subtypes include:
 - Follicular (solid and cystic)
 - Plexiform
 - Acanthomatous
 - Basal cell
 - Granular cell:
 - Histologic subtypes can be found independently or within the same tumor.
 - Have no bearing on treatment or prognosis except for the granular cell variant, which appears to be associated with increased recurrence rate
- Special stains are of limited utility in the diagnosis.

Differential Diagnosis

- Sinonasal nonkeratinizing carcinoma
- Basaloid squamous cell carcinoma
- Adenoid cystic carcinoma
- HPV-related carcinoma with adenoid cystic-like features
- Craniopharyngioma

Treatment and Prognosis

- Surgical excision is the preferred treatment in all cases:
 - Type and extent of surgery varies from conservative procedures such as polypectomy to more aggressive surgical procedures, including the Caldwell–Luc resection, lateral rhinotomy, and partial or radical maxillectomy.
- Recurrence of the tumor may occur within 1 to 2 years of the initial procedure but may occur years after initial surgery.
- Overall treatment success correlates with complete surgical eradication when performed in conjunction with thoroughly detailed radiographic imaging.
- No tumor deaths, metastases, or malignant transformation have been reported.

MALIGNANT NEOPLASMS OF THE NASAL CAVITY AND PARANASAL SINUSES

CARCINOMA OF THE NASAL VESTIBULE

- Carcinoma of the nasal vestibule is uncommon and considered to represent cutaneous carcinomas instead of mucosal carcinomas.
- More common in men than in women; occurs in age ranges from the sixth to ninth decades of life
- Tumors are located either in the nasal vestibule or at the mucocutaneous junction.
- Most common tumor type is squamous cell carcinoma:
 - Majority are keratinizing and well differentiated
- Cutaneous basal cell carcinomas may also occur but are uncommon.
- Cutaneous adnexal tumors may also occur in this location.
- No association with EBV or HPV
- The differential diagnosis for squamous cell carcinoma includes:
 - Cutaneous squamous papilloma
 - Schneiderian-type papillomas
 - Verrucous carcinoma

- Treatment includes local excision and/or radiotherapy.
- Staging follows AJCC system for primary cutaneous carcinomas excluding carcinoma of the eyelid:
 - T1: tumor 2 cm or smaller in greatest dimension with fewer than two high-risk features
 - T2: tumor >2 cm or any size with two or greater high-risk features
 - T3: tumor with invasion of the maxilla, mandible, orbit, or temporal bone
 - T4: tumor with invasion of the skeleton (axial or appendicular) or perineural invasion of skull base

NOTE: High-risk features refer to depth of invasion, perineural invasion, or high-grade histology.

- Wang classification of nasal vestibular carcinomas felt to be superior to AJCC classification regarding prognostic value and more relevant to use, as it is designed specifically for the nasal vestibule:
 - T1: limited to the nasal vestibule, relatively superficial, involving one or more sites
 - T2: extended from the nasal vestibule to adjacent structures, such as the upper nasal septum, upper

- lip, philtrum, skin of the nose, and/or nasolabial fold, but not fixed to the underlying bone
- T3: massive with extension to the hard palate, buccogingival sulcus, large portion of the upper lip, upper nasal septum, turbinate, and/or paranasal sinuses; fixed with deep muscle or bone involvement
- Most patients have an excellent prognosis:
 - 5-year results include:
 - Overall survival 50%
 - Cancer-specific survival 74%
 - Locoregional control 67%
- Cancer-specific survival according to Wang classification reported to be:
 - 83% for T1
 - 63% for T2
 - 39% for T3
 - For T1 tumors, 5-year locoregional control for surgery, surgery + radiotherapy (RT), or RT includes 94%, 87%, or 61%, respectively
 - Invasion of the subjacent nasal septal perichondrium or bone may occur.
 - Metastasis to cervical neck lymph nodes may occur but is uncommon.
- Carcinomas of the sinonasal tract account for approximately 3% of head and neck malignant neoplasms.
- In consideration of the entire sinonasal tract, malignant neoplasms originate (in descending order of occurrence) from:
 - Maxillary sinus (60%)
 - Nasal cavity (20% to 30%)
 - Ethmoid sinus (10% to 15%)
 - Sphenoid and frontal sinuses (1%)
- In consideration of the entire paranasal sinuses alone, malignant neoplasms originate (in descending order of occurrence) from:
 - Maxillary sinus (77%)
 - Ethmoid sinus (22%)
 - Sphenoid and frontal sinuses (1%)
- Causes of sinonasal malignant neoplasms include:
 - Occupational exposure to wood dust is linked to the development of sinonasal adenocarcinomas, intestinal types, and to a lesser extent squamous cell carcinoma.
 - Occupational exposure to nickel refining and chromate pigment manufacture is linked to an increased risk of sinonasal carcinoma.
 - Viruses including HPV and EBV: see below
- Premalignant lesions of the sinonasal tract:
 - Unlike other upper aerodigestive tract sites, in particular the oral cavity and larynx, isolated precursor lesions of the sinonasal tract (i.e., high-grade intraepithelial dysplasia and carcinoma in situ) are rarely seen unless associated with another neoplasm:
 - Often seen in association with an invasive squamous cell carcinoma, including conventional keratinizing type, nonkeratinizing carcinoma, basaloid squamous cell carcinoma
 - May be seen in association with a carcinoma arising in association with a benign neoplasm (e.g., malignant transformation of Schneiderian papilloma)
 - Although an extremely rare occurrence, sinonasal high-grade intraepithelial dysplasia can be seen in association with non-neoplastic sinonasal tract lesions such as inflammatory polyps.
 - Squamous cell carcinoma and variants thereof may develop from inverted and oncocytic types of Schneiderian papillomas:
 - HPV can be found in these types of Schneiderian papillomas, but there is no definitive link between the presence of HPV and the development of sinonasal squamous cell carcinoma.
 - There is no known association between the presence of squamous metaplasia of the sinonasal epithelium and the development of squamous cell carcinoma.

SINONASAL TRACT SQUAMOUS CELL CARCINOMA

General Considerations

- The epithelium lining of the sinonasal tract is capable of differentiating along various cell lines, accounting for the morphologic variety of carcinomas seen to arise from these surfaces, including squamous cell carcinoma, variants of squamous cell carcinoma, and adenocarcinomas.
- Squamous cell carcinomas of the upper aerodigestive tract mucosa are divided according to histologic subtype:
 - Most common type of squamous cell carcinoma of the sinonasal tract is the conventional type, including keratinizing and nonkeratinizing squamous cell carcinomas.
 - A number of “variants” of conventional squamous carcinoma may occur in the sinonasal tract, including papillary squamous cell carcinoma, verrucous carcinoma, spindle cell squamous carcinoma, basaloid squamous cell carcinoma, and adenosquamous carcinoma.
 - These variants of squamous cell carcinoma are sufficiently different in their pathologic features, biologic behavior, and therapeutic approach to merit separate discussion.
- Carcinomas of the sinonasal tract account for less than 1% of all malignant neoplasms.

- Viral-associated sinonasal carcinomas:
 - Human papillomavirus (HPV):
 - High-risk types of HPV now well-established as major etiologic factors in head and neck carcinomas especially of the oropharynx (see Section 3 for more complete discussion)
 - Transcriptionally active high-risk types of HPV are an important oncologic agent of certain carcinomas arising in the sinonasal tract.
 - HPV-associated sinonasal tract carcinomas proven to harbor transcriptionally active high-risk HPV by p16 immunohistochemistry and HPV DNA in situ hybridization (ISH) or polymerase chain reaction (PCR) include:
 - Nonkeratinizing carcinoma, as well as partially keratinizing squamous cell carcinoma
 - Basaloid squamous cell carcinoma
 - Papillary squamous cell carcinoma
 - Adenosquamous carcinoma
 - Adenoid cystic-like carcinoma
 - Rare examples of other sinonasal carcinoma types in which HPV identified by p16 immunohistochemistry and HPV DNA ISH or PCR include:
 - Small cell undifferentiated neuroendocrine carcinoma
 - Sinonasal undifferentiated carcinoma
 - In the oropharynx, HPV-associated carcinomas have distinct clinically epidemiologic and biologic characteristics (see Section 3 Pharynx for more complete discussion).
 - To date, it is yet to be determined if sinonasal carcinomas associated with HPV also have distinct clinically epidemiologic and biologic characteristics although appears HPV-associated nonkeratinizing carcinoma may have a better prognosis.
 - Epstein-Barr virus (EBV):
 - Extranodal NK/T-cell lymphoma, nasal type is associated with EBV (see later in this section).
 - Confirmation can be made by in situ hybridization for Epstein-Barr-encoded DNA (EBER).

SINONASAL SQUAMOUS CELL CARCINOMA

(Figs. 3-37 through 3-42)

Definition: Malignant epithelial neoplasm arising from the surface epithelium with squamous cell differentiation.

Synonyms:

- For keratinizing squamous cell carcinoma: sinonasal carcinoma; epidermoid carcinoma
- For nonkeratinizing squamous cell carcinoma: transitional carcinoma; respiratory epithelial

Fig. 3-37.

Sinonasal (maxillary sinus) keratinizing squamous cell carcinoma presenting with marked facial deformity, facial nerve paralysis, and orbital involvement.

carcinoma; Ringertz carcinoma; cylindrical cell carcinoma:

- Similar nonkeratinizing carcinomas of the oropharynx represent HPV-associated carcinomas, and such terminology (i.e., HPV-associated carcinoma) may in the future also be applicable for sinonasal nonkeratinizing carcinoma (for more complete discussion see Section 3, Pharynx).

Clinical

- Represents approximately 3% of head and neck malignant neoplasms and less than 1% of all malignant neoplasms
- Represents the most common type of malignant epithelial neoplasm of the sinonasal tract
- More common in men than in women; most frequently seen in the sixth and seventh decades of life, with 95% of cases arising in patients older than 40 years
- In decreasing order of frequency, the sites of occurrence include:
 - Antrum of the maxillary sinus > nasal cavity > ethmoid sinus > sphenoid and frontal sinuses
 - Although the frontal and sphenoid sinuses may be the sites of a primary carcinoma, most of the neoplasms involving these sinuses arise from the ethmoid sinus or from the nasopharynx.
 - Carcinoma of the nasal septum is extremely rare.
- Clinical presentations include facial asymmetry, unilateral nasal obstruction, epistaxis, a tumor mass palpable or visible in the nasal or oral cavity, pain, persistent purulent rhinorrhea, nonhealing sore or ulcer, and exophthalmos.
- Diagnosis of paranasal sinus carcinoma is often delayed as the clinical signs and symptoms in the earlier stages of disease are similar to those of chronic sinusitis, whereas the diagnosis of carcinoma of the

Fig. 3-38. Sinonasal squamous cell carcinoma.

Coronal CT scans (**A** to **C**) on three different patients show in **A**, an antral tumor that has destroyed the orbital floor and obstructed the antrum. The tumor has extended through the periorbita, which is noted by the infiltration of the extraconal fat planes in the lower orbit. In **B**, the antral tumor has destroyed more of the antral walls, obstructed the antrum, and more grossly infiltrated the orbit and the inferior musculature. In **C**, the tumor has caused even more bone destruction and infiltrated more of the orbit, causing clinical elevation of the left eye. In **D**, a coronal T2-weighted MR image shows a low signal intensity antral tumor that has destroyed the orbital floor and invaded the left ethmoid cells. The orbital invasion is extensive with infiltration of the inferior and medial muscles. All of these patients had maxillary squamous cell carcinomas. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 268, Fig. 4-23.)

nasal cavity is usually recognized relatively early as symptoms prompt earlier clinical detection.

- Radiology:
 - Nonexpansile mass causing sinus opacification with erosion and/or destruction of the sinus bony confines and extension to adjacent soft tissue structures
- Risk factors that have been associated with sinonasal tract squamous carcinoma include:
 - For keratinizing squamous cell carcinoma:
 - Cigarette smoking
 - Not associated with HPV
 - Occupational exposure, as well as exposure to textile dust and nickel, prior Thorotrast use, and development from Schneiderian papilloma
 - For nonkeratinizing or partially keratinizing:
 - Associated with high-risk HPV:
 - p16 positive (nuclear and cytoplasmic in >75% of tumor cells)
 - Transcriptionally active high-risk HPV identified by molecular analyses (ISH, PCR)

- In carcinomas arising in association with a Schneiderian papilloma, low-risk HPV may be found, but a direct cause and effect has not been definitively found.

- Patients with nasal cavity squamous carcinomas are at greater risk for a second primary malignancy either at another mucosal site in the upper aerodigestive tract or involving the nonhead and neck sites including lung, gastrointestinal tract, or breast.

Pathology

Gross

- Polypoid, papillary, fungating, or inverted growth patterns that may be well circumscribed, with an expansile growth and limited invasion, or necrotic and friable with a hemorrhagic appearance and destructive growth

Histology

- Sinonasal squamous cell carcinomas are histologically divided into keratinizing and nonkeratinizing subtypes.

Fig. 3-39. Sinonasal (maxillary sinus) keratinizing squamous cell carcinoma.

A, The carcinoma is invasive including into soft tissue structures; the histology of the invasive carcinomas may range from **(B)** well differentiated with cohesive tumor nests showing keratinization, intercellular bridges, and limited cytomorphic atypia. **C**, Moderately differentiated with cohesive tumor nests retaining their squamous cell appearance with individual cell keratinization and intercellular bridges but with greater nuclear pleomorphism with increased nuclear-to-cytoplasmic ratio and increased mitotic activity. **D**, Poorly differentiated with cohesive tumor nests with limited squamous cell features and marked nuclear pleomorphism and mitotic activity including atypical mitoses.

Fig. 3-40. Nonkeratinizing squamous cell carcinoma of the right maxillary sinus.

The patient presented with facial deformity with deviation of the nose to the left of midline and slight closure of the right eye.

Keratinizing Squamous Cell Carcinoma (SCC)

- Keratinizing SCC is the most common sinonasal carcinoma, representing 80% to 85% of all cases.
- Histologic grading includes well-differentiated, moderately differentiated, and poorly differentiated carcinoma.
- Well-differentiated squamous cell carcinomas are characterized by:
 - Readily apparent keratinization with keratin pearl formation or individual cell keratinization
 - Dyskeratosis (abnormal keratinization), which may be prominent
 - Intercellular bridges are identifiable.
 - Neoplastic cells showing mild to moderate nuclear atypia with enlarged, hyperchromatic nuclei and low mitotic activity
- Dysplasia of the adjacent or overlying surface epithelium may be seen; if present, the dysplasia may

Fig. 3-41. Nonkeratinizing squamous cell carcinoma.

Portion of resected specimen showing a bulging, tan-white mass in the maxillary sinus.

vary from low-grade (mild dysplasia) to high-grade dysplasia (i.e., moderate to severe); severe dysplasia is synonymous with carcinoma in situ.

- As a squamous cell carcinoma becomes less differentiated (higher histologic grade), the tumor shows less evidence of squamous differentiation including absence of keratinization and identifiable intercellular bridges and greater degree of anaplasia as well as increased mitotic activity, including atypical forms.
- Even in the poorly differentiated carcinomas, evidence of keratinization is usually focally present.
- Stromal invasion may include cohesive nests or cords of malignant cells or may be represented by isolated invasive malignant cells:
 - Host response to invasive carcinoma (desmoplasia) includes collagen deposition with or without an associated chronic inflammatory cell reaction.
- Immunohistochemistry:
 - Cytokeratins, p63 and p40 positive
 - p16 negative

Nonkeratinizing Squamous Cell Carcinoma

- Represents approximately 15% to 20% of all cases
- May also have a papillary or exophytic growth pattern but often shows a downward (inverted or

endophytic) growth with broad interconnecting bands or nests of neoplastic epithelium

- Tumor nests may have rounded or smooth borders or may be delineated by basement membrane-like material:
 - This pattern of growth is similar to that of bladder cancers, hence the designation of these tumors as transitional-type carcinoma.
 - Given the smooth borders or surrounding basement membrane-like material, these tumors may not be interpreted as invasive and may be underdiagnosed as papillomas with severe dysplasia/carcinoma in situ.
- This tumor type is composed of elongated cells with a cylindric or columnar appearance, oriented perpendicular to the surface and generally lacking evidence of keratinization; keratin may be present focally but does not represent a significant component of the tumor.
- In general, this is a hypercellular neoplasm characterized by nuclear pleomorphism, hyperchromasia, increased nuclear-to-cytoplasmic ratio, loss of cell polarity, and increased mitotic activity, including atypical forms although in any given case degree of nuclear pleomorphism and mitotic activity may not be high.
- Dysplasia of the adjacent or overlying surface epithelium may be seen; the dysplasia may vary from low-grade (mild dysplasia) to high-grade (moderate to severe dysplasia).
- Immunohistochemistry:
 - Cytokeratins, p63 and p40 positive
 - p16 positive (diffuse nuclear and cytoplasmic) – Reported in approximately 40% of cases
 - Neuroendocrine markers typically negative but patchy staining (e.g., synaptophysin, others) may be present
 - *SMARCB1* (INI-1) positive.

Differential Diagnosis

- Schneiderian papilloma, inverted type:
 - Growth characteristics seen in nonkeratinizing carcinoma, in particular presence of broad interconnecting or ramifying cords of tumor, are not the pattern seen in association with Schneiderian papilloma, inverted type; presence of such growth characteristics even in face of tumor with limited nuclear pleomorphism and increased mitotic activity should raise serious concern for diagnosis of nonkeratinizing carcinoma.
- ***SMARCB1* (INI-1)-deficient carcinoma of sinonasal tract:** (Figures 3.43)
 - *SMARCB1* (INI-1) tumor-suppressor gene located on chromosome 22q11.2
 - Gene product ubiquitously expressed in nuclei of normal tissues

Fig. 3-42. Nonkeratinizing squamous cell carcinoma.

A and **B**, The tumor originates from the surface epithelium and invades into the submucosa as broad interconnecting bands of the neoplastic epithelium growing down ("inverted") into the stroma. **C**, Focally, carcinoma in situ may be present. **D**, The neoplastic epithelium is nonkeratinizing; cells are elongated with a cylindric or columnar appearance, oriented perpendicularly to the surface. **E**, Marked cellular pleomorphism with loss of polarity, increased nuclear-to-cytoplasmic ratio, and increased mitotic activity. Similar to oropharyngeal nonkeratinizing carcinoma, this type of sinonasal carcinoma has been associated with human papillomavirus (HPV) and in the future may be referred to as a sinonasal HPV-associated (nonkeratinizing) carcinoma. **F**, Lesional cells show diffuse (nuclear and cytoplasmic) p16 immunoreactivity with subsequent confirmation by molecular analysis for the presence of transcriptionally active HPV.

Fig. 3-43. *SMARCB1* (INI-1)-deficient carcinoma of the sinonasal tract.

A and B, Tumor predominantly comprised of basaloid cells with enlarged round nuclei with inconspicuous to enlarged nucleoli and variable amount of cytoplasm; note the absence of significant nuclear pleomorphism although increased mitotic activity and necrosis commonly present (not shown); in **(B)** intermixed among the basaloid cells are cells with abundant, eccentric eosinophilic cytoplasm (*arrowheads*) imparting rhabdoid features. Immunohistochemical staining showed the lesional cells to be reactive for cytokeratins (not shown) with absence of **(C)** INI1 (nuclear) reactivity. Molecular analysis confirmed the loss of *SMARCB1* expression characterized by *SMARCB1* deletions by FISH. **D,** Two orange signals (CEN22) but no green signals (*SMARCB1*) in a majority of tumor cells indicating biallelic (homozygous) deletion of *SMARCB1* locus. One normal stromal spindle cell (likely fibroblast, *arrows*) showed intact two signals of both colors. (Slides for photography and image for part D provided by A. Agaimy, MD).

- Considered integral component of chromatin remodeling complex *SWI/SNF*
- Loss of nuclear *SMARCB1* expression characterizes heterogeneous family of neoplasms with highly varying histologic appearance and biological behavior including:
 - Pediatric atypical teratoid/rhabdoid tumors, malignant rhabdoid tumors of kidney and extrarenal tissues, renal medullary carcinoma, both types of epithelioid sarcoma, epithelioid malignant peripheral nerve sheath tumors, and some myoepithelial soft tissue neoplasms
 - In addition to these predominantly pediatric aggressive neoplasms defined by primary loss of *SMARCB1* expression as a consequence of deletions or mutations involving *SMARCB1* locus, secondary *SMARCB1* loss reported in carcinomas arising in different organs including gastrointestinal tract, pancreas, uterus and nervous system
- Common to most of these entities:
 - Loss of *SMARCB1* (INI-1) reactivity
 - Presence of rhabdoid cell component that varies from subtle (few scattered cells) to extensive comprising (almost entire neoplasm)

- Frequent although not uniformly aggressive clinical course with widespread metastasis at time of diagnosis
- *SMARCB1* gene inactivation implicated in pathogenesis of diverse group of malignant neoplasms that tend to share “rhabdoid” cytomorphology
- Recent reports document presence of *SMARCB1*-deficient carcinomas arising in sinonasal tract (9 total cases) characterized by:
 - Slight female predilection; occurrence in adults (mean in sixth decade of life)
 - Presence of nests, sheets, and cords of cells without any histologic evidence of specific cellular differentiation (e.g., squamous, glandular, other).
 - Primarily comprised of basaloid cells with scattered intermixed rhabdoid cells:
 - Basaloid cell nests and lobules with intervening desmoplastic stroma
 - Basaloid cells comprised of enlarged round nuclei with inconspicuous to enlarged nucleoli and scant cytoplasm
 - Rhabdoid cells characterized by abundant, eccentric eosinophilic cytoplasm:
 - Such cells may suggest plasmacytoid appearance and a possible diagnosis of a myoepithelial neoplasm
 - Generally absence of significant nuclear pleomorphism but increased mitotic activity (3 to 30 mitoses per 10 high power fields) and necrosis commonly seen
 - Additional features may include:
 - papilloma-like exophytic component
 - peripheral palisading, perivascular pseudorosettes
 - intraepithelial dysplasia (i.e., carcinoma in situ) may or may not be identified
 - extensive pagetoid surface growth with prominent denuding features
 - replacement of underlying mucous glands mimicking inverted papilloma
 - Immunohistochemical staining includes:
 - INI-1 negative staining in all cases:
 - Absence of INI1 reported in both invasive and in situ components
 - Consistent reactivity for cytokeratins (AE1/AE3, CK5) with diffuse or punctate paranuclear staining, latter reported relative to rhabdoid cells
 - Variable p63 and p40 reactivity with diffuse or focal nuclear staining
 - Vimentin reactivity varying from diffuse to scattered positive cells; rhabdoid cells with paranuclear dot-like pattern
 - Focal synaptophysin reactivity in majority of cases
- Variable expression for p16 but no evidence of transcriptionally active HPV by molecular analyses
- E-cadherin strong membranous reactivity
- Absence of S100 protein except for 1 reported case with focal staining
- No reactivity for chromogranin, smooth muscle actin and NUT protein marker
- Molecular biology:
 - Loss of *SMARCB1* expression characterized by *SMARCB1* deletions by FISH
 - Absence of EBV by in situ hybridization
- Differential diagnosis includes:
 - Nonkeratinizing squamous cell carcinoma
 - Sinonasal undifferentiated carcinoma
 - Schneiderian papilloma
 - NUT midline carcinoma
 - Myoepithelial carcinoma
- Treatment includes surgery and adjuvant chemoradiation
- Prognosis:
 - Majority of patients present with advanced clinical (and pathologic) stage disease (T4/pT4)
 - Local recurrences and/or distant metastases are common, including:
 - locoregional lymph nodes
 - distant visceral sites (liver, lung, pleural, pericardium)
 - Of patients reported to date, 8 with follow-up including:
 - 63% (5/8) dead of disease from 15 months to as long as 102 months
 - 4 alive without disease up to 84 months from diagnosis
 - 1 alive with disease at 70 months from diagnosis
- Inactivation of *SMARCB1* tumor-suppressor gene appears to be involved in pathogenesis of a subset of sinonasal carcinomas further expanding family of *SMARCB1*-deficient neoplasms

Treatment and Prognosis

- Treatment for sinonasal squamous cell carcinoma is complete surgical resection and adjuvant radiotherapy with or without chemotherapy:
 - Surgical advances now permit complex tumor removal and reconstruction surrounding these structures, resulting in functional and cosmetic improvements.
- Induction chemotherapy may be used in patients with advanced stage disease:
 - Favorable response to induction chemotherapy associated with better survival and reasonable chance of organ preservation.

- Local recurrences frequently occur, but metastatic disease is uncommon if the tumor is confined to the involved sinus:
 - Local failure remains the dominant cause of poor outcome.
 - Death due to disease usually the result of uncontrollable local recurrent disease
- Regional lymph node metastatic rate of approximately 15%:
 - Given central location, metastatic disease may occur to ipsilateral or contralateral lymph nodes.
 - Primary lymph node drainage is to submental and submandibular lymph nodes.
 - Secondary drainage to facial, superficial parotid, and deep cervical lymph nodes
- Owing to low rate of nodal metastases, regional lymph node dissection and/or radiation of regional lymph nodes not advocated as part of initial management protocol
- Tumor extension beyond the sinus wall results in a higher incidence of regional lymph node metastasis.
- In general, the prognosis is poor:
 - 5-year survival rates include:
 - 65% for carcinomas confined to nasal cavity
 - 45% for carcinoma of the maxillary antrum
 - Clinical stage is of more importance to prognosis than histologic type.
 - Factors portending a poorer prognosis include:
 - Higher clinical stage disease with involvement of more than one anatomic area
 - Extension beyond the nasal cavity or paranasal sinuses
 - Regional lymph node metastasis
- Presence of HPV associated with better disease-free survival and overall survival than non-HPV cancers
- Pattern of invasion may also affect prognosis:
 - Tumors with “diffuse spread” or single cell invasive growth pattern have a decreased survival of 30% to 40% as compared with 80% to 90% survival in patients with a more cohesive or “pushing” pattern of invasion.
 - Invasive cancers with single cell or small aggregates of tumor cells invading into the host stroma are much more capable of lymph-vascular invasion as compared with large cohesive tumor nests.
- TNM staging of sinonasal tract mucosal carcinomas applies only to the maxillary sinus (see [Table 3-2](#)).

VARIANTS OF SQUAMOUS CELL CARCINOMA

- Variants of conventional squamous cell carcinoma include:
 - Verrucous carcinoma
 - Papillary squamous cell carcinoma
 - Spindle cell squamous carcinoma

- Basaloid squamous cell carcinoma
- Adenosquamous carcinoma
- All of these variants may occur in the sinonasal tract but are more common in other mucosal sites of the head and neck.
- For a detailed discussion of these histologic variants, see appropriate sections including Section 2, Oral Cavity; Section 3, Pharynx; and Section 5, Larynx.

SINONASAL UNDIFFERENTIATED CARCINOMA (SNUC)

(Figs. 3-44 through 3-46)

Definition: Highly aggressive and clinicopathologically distinctive carcinoma of uncertain histogenesis that typically presents with locally extensive disease and is composed of pleomorphic tumor cells with frequent necrosis without evidence of squamous or glandular differentiation; neuroendocrine differentiation may or may not be present.

Synonym: Anaplastic carcinoma

Fig. 3-44. Sinonasal undifferentiated carcinoma (SNUC).

SNUCs typically are rapidly growing, usually presenting over weeks to months, and at the time of presentation frequently are widely invasive with destructive growth. Sagittal T1-weighted, fat-suppressed, contrast-enhanced MR image shows a large mass in the ethmoid and sphenoid sinuses. The remaining sphenoid sinus is obstructed. Some dural enhancement is also present. This patient had an SNUC. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 291, Fig. 4-78.)

Fig. 3-45. Sinonasal undifferentiated carcinoma.

A, Invasive tumor showing a lobular growth, a frequent feature of this tumor; the surface epithelium is attenuated (*upper left*), and it is uncommon to find evidence of carcinoma in situ and/or continuity of tumor to the surface epithelium. **B**, In addition to a lobular pattern, trabecular (as well as diffuse—not shown) growth may be identified. **C** and **D**, These tumors are markedly cellular and characterized by the presence of polygonal to oval-appearing cells composed of medium to large, round to oval, hyperchromatic to vesicular nuclei, inconspicuous to prominent nucleoli, and a varying amount of eosinophilic-appearing cytoplasm with poorly defined cell membranes; increased mitotic activity is present, including atypical mitoses and individual cell necrosis. **E**, Usually, prominent confluent foci of tumor necrosis is present. **F**, Diffuse cytokeratin immunoreactivity is present.

Clinical

- Considered an uncommon neoplasm but being recognized with greater frequency
- More common in men than in women; occur over a wide age range, including third to ninth decades of life, with a median at presentation in the sixth decade
- Typically, patients present with multiple symptoms that include nasal obstruction, epistaxis, proptosis, visual disturbances (e.g., diplopia), facial pain, and symptoms of cranial nerve involvement.

Fig. 3-46. SNUC.

Additional cytologic features that can be seen in sinonasal undifferentiated carcinomas include **(A)** the presence of cells with clear cytoplasm and **(B)** focal squamous cell differentiation. The latter if present must represent an extremely limited component of a tumor that otherwise shows unequivocal cytomorphic features and associated clinical parameters of sinonasal undifferentiated carcinoma. However, alternative diagnostic consideration in the face of an undifferentiated carcinoma with squamous differentiation would include NUT midline carcinoma.

- A characteristic clinical phenomenon is that patients with SNUC develop symptoms usually of a relatively short duration (weeks to months).
- Extensively infiltrative at presentation involving multiple sites, including the nasal cavity, one or more paranasal sinuses, orbit, skull base, and the brain
- Most patients have unilateral disease, but bilateral disease may occur.
- Radiology:
 - CT scan, MRI often demonstrate a large (sinonasal) mass typically with local invasive growth

extending beyond its bony confines with involvement of orbital and/or cranial bones.

- Intracranial extension may occur.
- SNUC is a tumor of uncertain histogenesis:
 - It seems reasonable that SNUC arises from the Schneiderian epithelium and therefore is of ectodermal derivation.
 - Although speculative, given overlapping clinical, light microscopic, immunohistochemical, and ultrastructural features with olfactory neuroblastoma and neuroendocrine carcinoma, the cell of origin may be related to the Schneiderian membrane and olfactory epithelia.
 - On the basis of finding neuroendocrine features by immunohistochemistry and electron microscopy, SNUC may be a neuroendocrine carcinoma with classification essentially equivalent to the pulmonary large cell (neuroendocrine) carcinoma; however, most authorities do not consider SNUC to be a variant of neuroendocrine carcinoma.
- There are no known etiologic agents:
 - SNUCs are typically negative for Epstein-Barr virus (EBV) even though there are reports of EBV RNA identified in Asian and Italian patients with SNUC but not in other Western patients with SNUC:
 - Such EBV-positive sinonasal carcinomas more likely are lymphoepithelial-like carcinomas (see later in this chapter).
 - HPV (by p16 immunohistochemistry and molecular analysis) identified in a limited number of SNUCs; uncertain relationship between HPV and SNUCs
 - Some cases have been reported to develop following radiation therapy for nasopharyngeal carcinoma.
 - Although no specific cause is linked to the development of SNUC, cigarette smoking and nickel exposure have been identified in patients with SNUC.
 - Deletion of the retinoblastoma gene has been implicated in the development of SNUC.

Pathology

Cytology

- Hypercellular smears with:
 - A single-cell-predominant pattern
 - Intermediate-sized cells with irregular nuclear contours and small nucleoli
 - Nuclear pleomorphism and mitotic figures present
 - Background of naked nuclei and karyorrhectic debris
 - Vacuoles or extracellular lumina may be identified.

Gross

- Usually large tumors typically measuring more than 4 cm in greatest dimension and tend to be fungating with poorly defined margins, and with invasion into adjacent structures and/or anatomic compartments, including bone destruction

Histology

- Characterized by submucosal cellular proliferation with varied growth, including trabecular, sheet-like, ribbons, solid, lobular, and organoid patterns.
 - Surface involvement may be seen in the form of severe dysplasia/carcinoma in situ, but often there is ulceration, which precludes evidence of surface epithelial derivation.
 - Cellular infiltrate consists of polygonal cells composed of medium to large-sized, round to oval, hyperchromatic to vesicular nuclei, inconspicuous to prominent nucleoli, and a varying amount of eosinophilic-appearing cytoplasm with poorly defined cell membranes, although distinct cell borders may be present; occasionally, cells with clear cytoplasm can be identified:
 - The nuclear-to-cytoplasmic ratio is high.
 - Increased mitotic activity is present, including atypical mitoses.
 - Often prominent tumor necrosis (confluent areas and individual cells) and apoptosis
 - Cell types may include:
 - Cells with round to oval hyperchromatic nuclei, inconspicuous to small nucleoli, and limited pink to amphophilic cytoplasm
 - Cells similar to those seen in nasopharyngeal undifferentiated carcinoma:
 - Cells with large vesicular nuclei and prominent nucleoli and associated lymphocytes
 - Reported to be seen predominantly in Asian patients but not exclusive to Asian patients
 - Large cell type with features similar to large cell carcinoma of the lung:
 - Large cells with pleomorphic nuclei, prominent eosinophilic nucleoli
 - Reported to be seen predominantly in Asian patients but is not exclusive to Asian patients
- NOTE:** Cell types described are not mutually exclusive but can be seen to a variable extent in a single tumor. Further, the increased mitotic activity and necrosis is present in all cell types.
- Lymph-vascular invasion and neurotropism are often present.
 - By definition, squamous or glandular differentiation is not present; however:
 - Squamous cell differentiation may be present without excluding the diagnosis of SNUC.

- The diagnosis of SNUC can still be retained in the presence of squamous differentiation if:
 - The squamous foci (keratinization and intercellular bridges) are limited in extent (e.g., less than 5%) and occur in a neoplasm where the dominant histologic features are those of SNUC
 - The clinical parameters are those associated with SNUC, including:
 - Rapid onset and tumor growth (weeks)
 - Presence of multiple symptoms that may include visual disturbances and symptoms of cranial nerve involvement
 - Extensively infiltrative at presentation involving multiple sinonasal tract (and adjacent) sites
 - Sinonasal squamous cell carcinoma and variants thereof usually do not present with the above clinical parameters, especially rapid onset and tumor growth over a few weeks.
- Neurofibrillary material and true neural rosettes are not identified.
- Histochemistry:
 - Noncontributory to diagnosis
 - Stains for epithelial mucin are negative.
- Immunohistochemistry:
 - SNUCs are consistently immunoreactive with epithelial markers, including pankeratins and simple keratins (i.e., CK7, CK8, and CK19); reactivity for pankeratins is often intense and diffuse.
 - CK4, CK5/CK6, and CK14 reported to be negative
 - Variable reactivity can be identified for p63:
 - Some cases scattered focal positive staining
 - Some cases negative
 - Less common is the presence of diffuse positivity.
 - p40 may be positive.
 - Less than half of the cases have been reported to be positive for epithelial membrane antigen, neuron specific enolase (NSE), or p53.
 - S100 protein rarely observed and never in the peripheral sustentacular cell pattern characteristically observed in olfactory neuroblastoma
 - Focal reactivity for synaptophysin, chromogranin, CD56, CD57 (Leu-7) may be seen.
 - Vimentin, calretinin, muscle markers (desmin, myoglobin, myf-4, actins) hematolymphoid markers (leukocyte common antigen, B- and T-cell), melanocytic cell markers (HMB-45, melana, tyrosinase), and CD99 (Ewing marker) are usually absent.
 - Absence of Epstein-Barr virus by immunohistochemical staining (LMP-1) and/or in situ hybridization for Epstein-Barr encoded RNA (EBER)

- Electron microscopy:
 - Rare membrane-bound, dense core neurosecretory granules have been noted, and poorly formed desmosomes may occasionally be found.
- Cytogenetics and molecular genetics:
 - Sex-determining region Y-Box 2 (SOX2) amplification detected in SNUCs as well as squamous cell carcinoma and carcinomas arising in inverted papillomas, suggesting that SNUCs are molecularly closely related to these other cancers
 - No other specific molecular profiling identified and SNUC remains a poorly characterized malignancy at the clinical and molecular level.

Differential Diagnosis

- Squamous cell carcinoma, keratinizing and nonkeratinizing types (Table 3-5)
- Olfactory neuroblastoma (high grade) (see Table 3-5)
- Small cell undifferentiated neuroendocrine carcinoma (see Table 3-5)
- Nasopharyngeal-type, nonkeratinizing undifferentiated carcinoma (see Table 3-5)
- Sinonasal-based lymphoepithelial carcinoma
- NUT midline carcinoma
- Mucosal malignant melanoma
- Nasal-type NK/T-cell lymphoma
- Rhabdomyosarcoma
- Ewing sarcoma family of tumors

NOTE: Although differences can be identified by light microscopic evaluation, often the differentiation of all these tumor types rests on the immunohistochemical staining profile for a given tumor (Table 3-6).

Treatment and Prognosis

- Multimodality therapy considered best treatment approach to provide best chance for survival and includes radical surgery and postoperative chemoradiotherapy
- Prognosis for patients treated with definitive radiotherapy ± chemotherapy considered less promising than for those receiving surgery and postoperative radiotherapy ± chemotherapy.
- HPV-positive SNUCs may benefit from improved survival, but this finding requires further substantiation.
- Generally considered a highly aggressive neoplasm with poor survival:
 - 5-year overall and disease-free survival rates of 45.2% and 50.7%, respectively, reported in one series (n = 19) with no significant difference between treatment types
 - Another series (n = 23) prognosis included:
 - Actuarial 5-year survival outcomes (n = 23) include:

- Progression-free survival, 42%
 - Cause-specific survival, 43%
 - Overall survival, 32%
- Actuarial 5-year disease control rates include:
 - Local control (in field or marginal), 74%
 - Local-regional control (excluding leptomeningeal spread), 58%
 - Regional control, 78%
 - Freedom from leptomeningeal recurrence, 72%
 - Distant metastasis-free survival, 73%
- Another series (n = 18):
 - 2-, 3-, and 4-year local control (LC), disease-free survival (DFS), and overall survival (OS) were:
 - 78%, 72%, and 56%
 - 75%, 65%, and 52%
 - 75%, 50%, and 48%
 - Trimodality treatment approach provided 83% local control and 92% distant metastasis-free survival
 - Other modalities provided 50% local control and 33% distant metastasis-free survival.
- Local recurrence is common and is the major cause of morbidity and mortality.
- Metastatic spread occurs to bone, brain, liver, and cervical lymph nodes.
- Causes of death primarily related to distant metastases and local invasion

NUT MIDLINE CARCINOMA (NMC) (Figs. 3-47 and 3-48)

Definition: Carcinoma characterized by squamous differentiation or expression of epithelial markers originating from midline epithelial structures with chromosomal rearrangements of the gene encoding nuclear protein in testis (NUT) at 15q14:

- Unique chromosomal translocation, which is the sole identifier of this disease
- t(15;19) results in a novel fusion oncogene, bromodomain-containing protein 4 (BRD4)-NUT
- Some patients harbor NUT with BRD4 gene break point (BRD4-NUT fusion).
- Some patients harbor NUT without BRD4 gene break point (NUT variant).

Synonym: Midline carcinoma with NUT rearrangement

Clinical

- Rare neoplasm with less than 30 cases reported in the literature

TABLE 3-5 Comparison of Sinonasal Undifferentiated Carcinoma (SNUC), Olfactory Neuroblastoma, High-Grade (ONB, HG), SNT Keratinizing Squamous Cell Carcinoma (SCC), SNT Nonkeratinizing Squamous Cell Carcinoma (NKSCC), Nasopharyngeal Carcinoma, Nonkeratinizing Undifferentiated Type (NPC), and Small Cell Undifferentiated Neuroendocrine Carcinoma (SCUNC)

	SNUC	ONB, HG	SCC	NKSCC	NPC	SCUNC
Site(s)	SNT usually more than one site	Roof of nasal cavity	Maxillary > nasal > other sinuses	Maxillary > nasal > other sinuses	Nasopharynx	Superior or posterior nasal cavity often with extension into adjacent paranasal sinuses (e.g., maxillary and ethmoid sinuses)
Onset	Rapid (weeks to months)	Not rapid	Not rapid	Not rapid	Not rapid; may present as an occult metastasis to cervical lymph nodes	Not rapid
Intraepithelial premalignant lesion	Typically absent but may be present	Absent	Present	Present	Typically absent but may be present	Typically absent but may be present
Squamous differentiation	Absent	Absent	Present	May be present	Absent	May be present
Pseudorosettes	Absent	Present in histologic grades 1, 2	Absent	Absent	Absent	Absent
True neural rosettes	Absent	Present in histologic grades 3, 4	Absent	Absent	Absent	May be present
CK (AE1/AE3, CAM5.2, CK5/6, OSCAR)	Positive, diffuse and strong although CK5/6 reported as negative in a limited number of cases reported	Negative; scattered lesional cells may be very focally positive	Positive, diffuse and strong	Positive, diffuse and strong	Positive, diffuse and strong	Positive often with punctuate (paranuclear) staining
p63	Variable ranging from negative to focally positive to rare cases extensively positive	Negative	Positive	Positive	Positive	Variably positive
Synaptophysin	Negative	Positive	Negative	Negative	Negative	Positive
S100 protein	Negative although scattered cells may be positive	Characteristic staining along periphery of neoplastic lobules; lesional cells may also be positive	Negative	Negative	Negative	Often positive
NSE	Positive in 50% of cases but typically focal	Consistently positive, diffuse and strong	Negative	Negative	Negative	Positive
p16	Negative but rarely reported as positive	Negative	Negative	Positive; transcriptionally active virus confirmed by ISH or PCR	Negative	May be positive
EBER	Negative	Negative	Negative	Negative	Positive	Negative

EBER, In situ hybridization for Epstein-Barr encoded RNA; SNT, sinonasal tract.

Pseudorosettes, also known as Homer Wright Rosette; True Neural Rosettes, also known as Flexner-Wintersteiner rosettes.

CALR, Calretinin; *CK*, cytokeratins (broad spectrum and simple); *DES*, desmin; *EBER*, in situ hybridization for Epstein-Barr encoded RNA; *EFT*, Ewing sarcoma family of tumors; *LCA*, leucocyte common antigen; *MMM*, mucosal malignant melanoma; *MSM*, melanoma specific markers (HMB45, MelanA, MITF1; tyrosinase); *myf-4*, myogenin (nuclear); *NK/T ML*, nasal-type NK/T cell malignant lymphoma; *NSE*, neuron specific enolase; *ONB*, olfactory neuroblastoma; *R+*, rarely positive; *RMS*, rhabdomyosarcoma; *S100*, S100 protein; *SCC*, squamous cell carcinoma; *SCUNC*, small cell undifferentiated neuroendocrine carcinoma; *SNUC*, sinonasal undifferentiated carcinoma; *SYN*, synaptophysin; *T/NL ML*, nasal type T/NK cell lymphoma; v, variably positive; *VIM*, vimentin.

+, positive; –, negative.

*Cytokeratin staining may be focally positive.

†Paranuclear punctate staining pattern often present.

‡Positive in nonkeratinizing carcinoma or partly keratinizing carcinoma; transcriptionally active virus confirmed by molecular analysis.

§Positive in the peripherally situated sustentacular cells.

**Fig. 3-47.** NUT midline carcinoma.

A, Sheets of undifferentiated cells separated by desmoplastic (fibrotic) stroma. **B**, Rather monotonous appearing neoplastic cells with limited nuclear pleomorphism comprised of round to oval nuclei, vesicular chromatin, prominent nucleoli and a minimal amount of amphophilic to eosinophilic appearing cytoplasm; mitotic figures are present (arrow). **C**, Tumor necrosis, including individual cell and/or large confluent foci. **D**, Cystic change with subtle (abrupt) squamous differentiation (arrows) lying adjacent to immature neoplastic cells. (Courtesy C. French, MD.)

Fig. 3-48. NUT midline carcinoma.

Immunohistochemistry findings include (A) diffuse reactivity (nuclear staining) for antibodies to NUT protein, (B) cytokeratin (AE1/AE3) positivity, and (C) p63 positive (nuclear staining). D, Fluorescent in situ hybridization (FISH) break-apart probe for the NUT gene is diagnostic. (A-C, Courtesy C. French, MD. D, From Orkin S et al: *Oncology of infancy and childhood*, Philadelphia, 2009, Saunders, Fig. 5-15.)

- Slightly more common in women than in men; predominantly affects children and young adults ranging in age from 3 to 35 (median 17.6 years)
- Predominantly but not exclusively occurs in sites above the diaphragm; sites of involvement include:
 - Head and neck:
 - Most common in sinonasal tract
 - Less common sites of occurrence include nasopharynx, larynx (supraglottic larynx and epiglottis), orbit, parotid gland, and tonsils
 - Thorax (mediastinum/thymus > lung and trachea)
 - Urinary bladder
- Symptoms generally related to a mass including obstruction
- There are no known etiologic agents.

Pathology

Gross

- Usually received piecemeal so there are no specific macroscopic findings:
 - Friable tissue fragments with or without necrosis

Histology

- Sheets, ribbons, and/or nests of undifferentiated cells separated by desmoplastic (fibrotic) stroma
- Lesional cells include round to oval nuclei with irregular contours, vesicular chromatin, prominent nucleoli, and a minimal amount of amphophilic-to eosinophilic-appearing cytoplasm:

- Minimal nuclear pleomorphism may be present including cells with monotonous appearance; however, marked nuclear pleomorphism may be present.
- Increased mitotic activity is present and necrosis, including individual cell and/or large confluent foci, may be identified.
- Foci of squamous differentiation frequently present:
 - May be distinct or subtle
 - Mature (well-differentiated) nests of squamous cells and extracellular keratin
 - Foci of squamous differentiation may appear abruptly, lying adjacent to sheets of immature cells.
 - Cystic change of squamous areas may occur.
 - Squamous differentiation is not predictive of the partner gene.
- Immunohistochemistry:
 - Diffuse reactivity (nuclear staining) for antibodies to NUT protein
 - Cytokeratins are positive, including AE1/AE3, CAM 5.2, PanK, CK7, and CK20:
 - Staining may be focal.
 - EMA consistently positive
 - p63 positive
 - p40 may be positive.
 - CD34 may be positive:
 - Initially considered a characteristic feature but no longer felt to be unique or specific
 - Unusual finding for an epithelial neoplasm
 - May be synaptophysin positive but generally negative for neuroendocrine markers (chromogranin, CD56, CD57) and NSE
 - No reactivity for hematolymphoid markers, myogenic markers (desmin, myoglobin, myf-4), actins, S100 protein, HMB45, calretinin, placental alkaline phosphatase (PLAP), alpha fetoprotein, and CD99
 - No known association with HPV or EBV
- Electron microscopy:
 - Composed of cells with large, irregularly shaped nuclei, prominent compact nucleoli, and abundant cytoplasm containing prominent bundles of tonofilaments, occasional clusters of pleomorphic granules, small numbers of lipid inclusions, and rare glycogen deposits
 - Cells exhibit stubby microvillous projections, intermittently enveloped by basal lamina, and interjoined by numerous well-formed desmosomal-type junctions and occasional junctional complexes.
- Cytogenetics and molecular genetics:
 - Translocation involving the NUT gene is (15;19)(q13;p13.1):

- Translocation fuses the NUT gene on chromosome 15 to the *BRD4* gene.
- In approximately one third of cases the NUT gene fuses to a different gene referred to as NUT-variant midline carcinoma.
- Function of the NUT protein is not known.
- Fluorescent in situ hybridization (FISH) using break-apart probe for the NUT gene is diagnostic.

Differential Diagnosis

- Olfactory neuroblastoma (high grade)
- Small cell undifferentiated neuroendocrine carcinoma
- Nasopharyngeal-type undifferentiated carcinoma
- Sinonasal undifferentiated carcinoma
- Mucosal malignant melanoma
- Nasal-type NK/T-cell lymphoma
- Rhabdomyosarcoma
- Ewing sarcoma family of tumors

Treatment and Prognosis

- No established treatment protocols
- Combination multidrug chemotherapy and radiation is most frequent treatment modality.
- Highly lethal despite intensive therapies:
 - Average survival of less than 1 year
- Novel treatment with bromodomain inhibitors and histone deacetylase inhibitors, both of which induce differentiation and growth arrest of NMC cells in vitro and in vivo, being tested in clinical trials for treating patients with NMC.
- Distant metastases may include to bone, lung, pleura, kidney, adrenal, lymph nodes, and skin.
- NUT variant carcinomas may have a less fulminant clinical course.

SINONASAL LYMPHOEPITHELIAL-LIKE CARCINOMA (Fig. 3-49)

Definition: Rare sinonasal tract carcinoma that is morphologically similar to its better known histologic counterpart in the nasopharynx.

Clinical

- Primarily affects men in the fifth to seventh decades of life
- More common in the nasal cavity than the paranasal sinuses
- Clinical presentation includes nasal obstruction, epistaxis, and, in the presence of invasive growth, proptosis and cranial nerve palsies.

Fig. 3-49. Sinonasal lymphoepithelial-like carcinoma.

A, Polypoid lesion with invasive growth with broad interconnecting cords of tumor similar to the growth pattern seen in sinonasal nonkeratinizing carcinoma. The lesional cells include **(B)** epithelioid-appearing cells and **(C)** spindle-shaped cells. Both cell types comprise enlarged vesicular nuclei and prominent eosinophilic nucleoli. Increased mitotic activity is present. **D**, Lesional cells are immunoreactive for cytokeratin (AE1/AE3). **E**, In situ hybridization for Epstein Barr-encoded RNA (EBER) show diffuse nuclear reactivity.

- Similar to its nasopharyngeal counterpart, there is a strong association with Epstein-Barr virus (EBV).

Pathology

Histology

- Histologic findings are similar to those of nasopharyngeal carcinoma, nonkeratinizing, undifferentiated type (see Section 3, Pharynx).
- Immunohistochemical reactivity:
 - Cytokeratins are positive.
 - Strong expression of EBV-encoded RNA (EBER) in most cases

Differential Diagnosis

- Sinonasal undifferentiated carcinoma:
 - Presence of EBV excludes a diagnosis of SNUC.
- Nasopharyngeal carcinoma, nonkeratinizing, undifferentiated type:
 - It is imperative to exclude sinonasal involvement from a nasopharyngeal primary tumor, and to this end, detailed clinical evaluation of the nasopharynx is indicated.
- Mucosal malignant melanoma
- Non-Hodgkin lymphoma

Treatment and Prognosis

- Prognosis is favorable owing to a good response to local radiotherapy.
- Regional cervical lymph node metastasis may be present at presentation.
- Favorable prognosis is not altered even in the presence of nodal metastasis.

HUMAN PAPILLOMAVIRUS (HPV)-RELATED CARCINOMA WITH ADENOID CYSTIC-LIKE FEATURES (Figs. 3-50 and 3-51)

Definition: Recently described and defined type of sinonasal carcinoma with morphologic features suggestive of adenoid cystic carcinoma and immunohistochemical evidence of myoepithelial differentiation but with features distinctly unusual for adenoid cystic carcinoma, including presence of surface intraepithelial dysplasia, absence of MYB gene rearrangement, and association with HPV.

Clinical

- Rare tumor with limited numbers of cases reported in the literature to date
- More common in women than in men; occur over a wide age range including 40 to 73 years (mean 55 years)

- Presenting symptoms include nasal obstruction and epistaxis; less commonly, epiphora may occur.
- Sites of occurrence include nasal cavity and/or paranasal sinuses, including ethmoid > maxillary and/or sphenoid; orbital involvement may occur.

Pathology

Gross

- Range in size from 1 cm to greater than 5.4 cm; mean 3 cm

Histology

- Invasive hypercellular lesion with solid, lobular, and nested growth separated by fibrous stroma
- Cribriform and microcystic growth, as well as true ductal structures present:
 - Microcystic spaces filled with basophilic material
 - Ductal structures represent a minor component.
- Neoplastic infiltrate includes two cell types:
 - Basaloid cells predominate, characterized by hyperchromatic and angulated nuclei, scant cytoplasm, and increased nuclear-to-cytoplasmic ratio with marked increase in mitotic activity; tumor necrosis and perineural invasion may be present, but lymph-vascular invasion not reported
 - True duct cells appear cuboidal with eosinophilic cytoplasm:
 - Often located at center of lobules surrounded by zones of basaloid cells
- Intraepithelial dysplasia of the surface epithelium present in majority of cases
- Invasive component lacks squamous differentiation
- Immunohistochemistry:
 - Cytokeratin (AE1/AE3) positive in all cases:
 - Strong in duct cells
 - Relatively weaker in basaloid cells
 - Basaloid cells express (usually strong and diffuse) one or more myoepithelial-related markers including p63, calponin, S100 protein, and/or actin.
 - CD117 (c-kit) consistently reactive:
 - Usually limited to ductal cells but occasionally may be diffuse
 - Strong and diffuse p16 reactivity (nuclear)
- HPV DNA in situ hybridization present with hybridization signals distributed:
 - Throughout basaloid cells and ductal cells
 - In surface dysplasia and invasive component
- Quantitative PCR confirmatory of high-risk HPV including HPV33 and less often HPV35.

Fig. 3-50. HPV-related carcinoma with adenoid cystic-like features.

A, Invasive hypercellular lesion with solid, lobular, and nested growth separated by fibrous stroma. **B**, Cribriform growth. **C**, Microcystic spaces filled with basophilic material. **D**, The neoplastic cells include a predominant basaloid cell population characterized by hyperchromatic and angulated nuclei, scant cytoplasm, as well as true ducts composed of cuboidal cells with eosinophilic cytoplasm. **E**, Increased mitotic activity (*arrowheads*) is present. **F**, Intraepithelial dysplasia of the surface epithelium.

Fig. 3-51. HPV-related carcinoma with adenoid cystic-like features.

Immunohistochemical findings include (A) cytokeratin (AE1/AE3) strong in duct cells and relatively weaker in basaloid cells; (B) basaloid cells show strong and diffuse p63 reactivity but ductal cells are negative; (C) basaloid cells show S100 protein reactivity; (D) strong and diffuse p16 reactivity.

Differential Diagnosis

- Adenoid cystic carcinoma, solid variant
- HPV-associated carcinomas:
 - Nonkeratinizing carcinoma
 - Basaloid squamous cell carcinoma

Treatment and Prognosis

- Treatment options include surgical resection alone, surgery plus postoperative radiotherapy, or combined chemoradiation therapy.
- Given limited long-term follow-up reported in the literature, the true biologic nature of this neoplasm is yet to be determined; cases identified in the literature, albeit with limited follow-up periods (median 15 months), most patients were alive without evidence of disease or with local recurrence.

OLFACTORY NEUROBLASTOMA (ONB) (Figs. 3-52 through 3-60)

Definition: Malignant neuroectodermal neoplasm thought to arise from the olfactory membrane of the sinonasal tract.

Synonyms: Esthesioneuroblastoma; esthesioneurocytoma; esthesioneuroepithelioma; esthesioneuroma; olfactory placode tumor

Clinical

- Uncommon malignant neoplasm representing approximately 2% to 3% of sinonasal tract tumors
- No gender predilection; occurs over a very wide age range from 3 years to the ninth decade, with a bimodal peak in the second and sixth decades of life

Fig. 3-52. Olfactory neuroblastoma.

Patient with a huge olfactory neuroblastoma destroying much of the soft tissue and bony structures between the upper nasal cavity and its appearance along the bridge of the nose resulting in marked facial deformity.

- Main presenting symptoms include unilateral nasal obstruction and epistaxis; less common manifestations include anosmia, headache, pain, excessive lacrimation, proptosis, and ocular disturbances.
- Most common site of occurrence is the upper nasal cavity in the area of the cribriform plate; often there is involvement of the ethmoid sinus:
 - “Ectopic” origin in the lower nasal cavity, within one of the paranasal sinuses (e.g., maxillary sinus) and nasopharynx, may occur.
- May uncommonly be associated with:
 - Syndrome of inappropriate antidiuretic hormone secretion (SIADH):
 - Resolution of SIADH expected following treatment of ONB
 - Absence of resolution of SIADH may be indicative that entire tumor has not been excised.
 - Resolution of SIADH with subsequent recurrence during follow-up suggests recurrence of ONB.
 - Cushing syndrome:
 - Resulting from ectopic ACTH production
 - High ACTH levels and plasma and urine cortisol levels dramatically dropped following multimodality management of ONB
- Radiology:
 - A sinonasal mass causing sinus opacification with or without bone erosion may be seen.
 - May be associated with calcifications, which produce a speckled pattern by radiographic analysis.
 - MRI studies demonstrate the presence of a vascular lesion with enhancement following gadolinium injection as seen on T1-weighted imaging:
 - T1-weighted imaging with gadolinium injection considered optimum method for assessing extent of disease prior to craniofacial resection.

Fig. 3-53. Olfactory neuroblastoma.

Axial (A) and sagittal (B) T1-weighted, fat-suppressed, contrast-enhanced MR images show a large, enhancing sinonasal mass that obstructs the frontal and sphenoid sinuses and extends intracranially. There is a tumoral large cyst at the intracranial margin of the tumor. This patient had an olfactory neuroblastoma. C, Axial T1-weighted, contrast-enhanced MR image on a patient who previously had a craniofacial resection for an olfactory neuroblastoma. There is a large enhancing recurrence extending into the orbits and the anterior cranial fossa. Note the small, broad-based cyst at the intracranial margin of the tumor. Such a cyst is highly suggestive of the diagnosis. This patient had an olfactory neuroblastoma. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 288, Fig. 4-72.)

Fig. 3-54. Olfactory neuroblastoma.

Coronal T1-weighted (A), T1-weighted, fat-suppressed, contrast-enhanced (B) MR images and a coronal CT scan (C) show an expansile left antral mass that extends into the left nasal cavity and ethmoid complex. The mass elevated the left orbital floor, but there is no gross invasion of the orbit. There is no intracranial extension. Extensive tumoral calcifications are present within the olfactory neuroblastoma. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 289, Fig. 4-73.)

- No known etiologic agent(s):
 - Administration of diethylnitrosamine to hamsters and *N*-nitrosopiperidine to rats produces nasal tumors that are histologically identical to ONB.
 - Conflicting data regarding the inclusion of ONB in the category of PNET:

Fig. 3-55.

Normal olfactory mucosa showing a bipolar surface epithelium overlying submucosa that includes seromucous glands referred to as Bowman's glands.

- Classically, PNET shows reactivity with monoclonal antibodies that recognize the Ewing sarcoma cell surface glycoprotein p30/32 and t(11;22) translocation with *EWS/FL1* gene fusion.
- Based on these features of PNET, the t(11;22) translocation reported in ONB and the presence of *EWS/FLI1* gene fusion in ONB would support the inclusion of ONB within the spectrum of PNET related to Ewing sarcoma.
- Other studies using immunohistochemistry, fluorescent in situ hybridization, and reverse transcriptase PCR have failed to identify these “markers” of PNET, thereby failing to confirm this translocation in ONB.
- ONB should be seen as distinct entity from PNET and the Ewing sarcoma family of tumors.
- ONB takes origin from the olfactory neuroepithelium that in the human fetus is found in the upper one third to one half of the nasal septum, the cribriform plate, and the superior-medial surface of the superior turbinate:
 - With aging, the olfactory epithelium degenerates and is replaced by respiratory epithelium.
 - The olfactory neuroepithelium is composed of bipolar sensory neurons, supporting cells, and the reserve (basal) cells.
 - Basal cells are mitotically active and are the presumed progenitor of ONB.

Pathology

Gross

- Glistening, mucosa-covered, soft, polypoid mass varying from a small nodule less than 1 cm to a mass

Fig. 3-56. Olfactory neuroblastoma (ONB), grade I.

A, Common to all grades of ONB is a characteristic lobular growth pattern, although in the higher histologic grade neoplasms, the lobular growth but may only be focally present. **B**, Lobular pattern with lobules separated by fibrovascular stroma; tumor nests include small round cells with a pink matrix, the latter representing neurofibrillary matrix seen in these tumors. **C** and **D** The neoplastic cells are well differentiated with uniform round to vesicular nuclei surrounded by abundant neurofibrillary material suggesting cytoplasmic extensions; mitotic figures are rarely seen.

Fig. 3-57. ONB, grade II.

A, Lobule growth is present with neoplastic cells surrounded by a neurofibrillary matrix, which is less well defined as compared with grade I ONB. **B**, The cellular component of grade II demonstrates greater pleomorphism as compared with the features seen in ONB, grade I.

Fig. 3-58. ONB, grades III and IV.

A, In grade III tumors the neoplastic cells demonstrate greater nuclear pleomorphism, less to absent neurofibrillary component as compared with grades I or II ONB. **B**, In grade IV tumors, the cells are the most undifferentiated of all the histologic grades, with anaplasia characterized by hyperchromatic, pleomorphic nuclei, indistinct cytoplasm, increased mitotic activity, including atypical mitoses; neurofibrillary matrix is absent, making identification of this neoplasm as an ONB difficult, with the diagnosis often hinging on location of the tumor and the immunohistochemical antigenic profile.

filling the nasal cavity, with possible extension into adjacent paranasal sinuses and nasopharynx

Histology

- Histologic appearance is divided into four grades as defined by Hyams (Table 3-7):

Grade I

- Most differentiated
- Architecture is lobular with intercommunication between lobules.
- Neoplastic cells are well differentiated with uniform round to vesicular nuclei with or without nucleoli and have indistinct borders.

Fig. 3-59. ONBs are associated with the presence of rosettes.

This illustration contrasts (*left*) the Homer Wright pseudorosettes seen in grades I and II ONBs and characterized by grouping of cells in a circumferential fashion around neurofibrillary matrix but without a defining basement membrane with (*right*) Flexner-Wintersteiner true neural rosettes in which cells align in a glandular fashion around spaces lined by distinct cell membranes.

- The nuclei are surrounded by neurofibrillary material:
 - Represents key diagnostic feature for diagnosis
 - Appears as fibrillary intercytoplasmic background
 - Corresponds to neuronal cell processes seen ultrastructurally
- Pseudorosette pattern (Homer Wright rosettes) is frequently seen.
- Varying amounts of calcification may be noted.
- Interlobular fibrous stroma is often extremely vascular.
- Mitotic activity and necrosis are absent.

Grade II

- Share many of the histologic features described for grade I lesions, but the neurofibrillary element is less well defined, and the neoplastic nuclei show increased pleomorphism.
- Scattered mitoses can be seen.

Grade III

- Retain a lobular architecture with an interstitial vascular stroma
- These tumors are characterized by a hypercellular neoplastic cell proliferation, in which the cells are more anaplastic and hyperchromatic and have increased mitotic activity as compared with grade I or II tumors.

Fig. 3-60. ONB, immunohistochemical findings.

The most consistent immunomarkers include **(A)** neuron specific enolase (NSE) showing diffuse and intense nuclear and cytoplasmic staining and **(B)** S100 protein typically in a peripheral (sustentacular cell-like) staining pattern. **C**, In higher grade ONBs, S100 protein positive staining is markedly decreased with sparse positive cells still mostly distributed along the periphery of the tumor nests. Usually ONBs are cytokeratin negative, and when cytokeratin is present it is often focal; this finding contrasts with sinonasal undifferentiated carcinoma, which has overlapping histologic features with the higher grade ONBs but is consistently cytokeratin positive, and NSE and S100 protein negative; if S100 protein is positive in SNUC it is not in a peripheral cell distribution as occurs in ONB. **D**, Calretinin staining is present in ONBs but is negative in other sinonasal small round cell malignant neoplasms.

TABLE 3-7 Hyams' Histologic Grading System for Olfactory Neuroblastoma

Histologic Features	Grade 1	Grade 2	Grade 3	Grade 4
Architecture	Lobular	Lobular	± Lobular	± Lobular
Pleomorphism	Absent to slight	Present	Prominent	Marked
NF matrix	Prominent	Present	May be present	Absent
Rosettes	Present*	Present*	May be present [†]	May be present [†]
Mitoses	Absent	Present	Prominent	Marked
Necrosis	Absent	Absent	Present	Prominent
Glands	May be present	May be present	May be present	May be present
Calcification	Variable	Variable	Absent	Absent

NF, Neurofibrillary.

*Homer Wright rosettes (pseudorosettes).

[†]Flexner-Wintersteiner Rosettes (true neural rosettes).

- Necrosis is present.
- Neurofibrillary component may be focally present but is much less conspicuous as compared with grades I or II tumors.
- True neural rosettes (Flexner–Wintersteiner rosettes) may be seen; however, in general, these structures are uncommonly identified.
- Calcification is absent.

Grade IV

- May also retain the overall lobular architecture, but the neoplastic element is the most undifferentiated and anaplastic of all the histologic grades.
- In these high-grade tumors, the cellular infiltrate is characterized by pleomorphic nuclei, often with prominent eosinophilic nucleoli and indistinct cytoplasm.
- Necrosis is commonly seen and there is increased mitotic activity, including atypical mitoses.
- True neural rosettes may be seen but, as in grade III tumors, are uncommon.
- Neurofibrillary component is generally absent.
- Calcification is absent.
- ONB may coexist with foci of adenocarcinoma, squamous carcinoma, or undifferentiated carcinoma, and in such circumstances may be referred to as mixed ONB and olfactory carcinoma:
 - It has been proposed that the basal cells of the olfactory epithelium may represent progenitor for these mixed neoplasms.
 - Alternatively, these mixed tumors may originate from the seromucous glands (Bowman's glands) lying subjacent to the olfactory epithelium.
- In general, the lower grade ONB are readily recognizable and diagnosable by light microscopy. Adjunct studies, particularly in the higher histologic grade tumors, may assist in the diagnosis.
- Histochemical stains have been replaced by immunohistochemistry in the diagnosis of ONB.
- Immunohistochemistry:
 - Most consistent marker is neuron specific enolase (NSE).
 - S100 protein staining seen in scattered lesional cells but shows characteristic staining of cells situated along the periphery of the neoplastic lobules (sustentacular cell-like pattern of staining), suggesting Schwann cell differentiation:
 - Consistently seen in lower histologic grade tumors
 - May only be focally present in higher histologic grade tumors
 - Peripheral S100 protein staining not usually a feature of other sinonasal malignancies considered in the differential diagnosis of ONB
 - Calretinin shown to be consistently reactive in ONB:
 - Calretinin nonreactive in other sinonasal small round cell malignant neoplasms
 - Reactivity is also present in a majority of cases for synaptophysin, neurofilament protein (NFP), class III beta-tubulin, and microtubule-associated protein.
 - Variable immunoreactivity present for chromogranin, glial fibrillary acidic protein (GFAP), and CD57 (Leu-7)
 - Cytokeratin is usually negative; some cases can show positive cells in a patchy, punctate fashion:
 - Diffuse staining is not typical for ONB, and the presence of diffuse staining should prompt consideration of alternative diagnoses including (but not limited to) sinonasal undifferentiated carcinoma and ectopic pituitary adenoma.
 - With additional findings could represent an olfactory carcinoma (see below)
 - Epithelial markers, including epithelial membrane antigen (EMA), p63, and carcinoembryonic antigen (CEA), are typically absent:
 - Focal p63 staining may be present.
 - Hematolymphoid markers (CD45, B-cell, and T-cell), CD56, melanoma markers (HMB-45, melan A, tyrosinase), myogenic markers (desmin, myoglobin, myf-4), CD99 are absent
 - Absence of HPV or EBV
- Electron microscopy:
 - Useful adjunct in the diagnosis and reveals the presence of dense-core neurosecretory granules measuring from 80 to 250 nm in diameter
 - Neurofilaments and neurotubules, and occasionally Schwann-like cells, can be seen.
- Cytogenetics and molecular genetics:
 - Comparative genomic hybridization (CGH) show high-level genomic instability with many chromosomal deletions and gains.

Differential Diagnosis

- Sinonasal undifferentiated carcinoma
- Small cell undifferentiated neuroendocrine carcinoma
- Nasopharyngeal-type undifferentiated carcinoma
- Sinonasal-based lymphoepithelial-like carcinoma
- Squamous cell carcinoma, keratinizing and nonkeratinizing types
- Mucosal malignant melanoma
- Nasal-type NK/T-cell lymphoma
- Rhabdomyosarcoma
- Ewing sarcoma family of tumors
- NUT midline carcinoma

NOTE: Although differences can be identified by light microscopic evaluation, often the differentiation of

TABLE 3-8 Clinical (Kadish) Staging for Olfactory Neuroblastoma

Stage	Extent of Tumor	5-Year Survival
A	Tumor confined to the nasal cavity	75% to 91%
B	Tumor involves the nasal cavity plus one or more paranasal sinuses	68% to 71%
C	Extension of tumor beyond the sinonasal cavities	41% to 47%

TABLE 3-9 Modified Kadish Staging for Olfactory Neuroblastoma

Stage	Extent of Tumor
A	Tumor confined to the nasal cavity
B	Tumor involves the nasal cavity plus one or more paranasal sinuses
C	Extension of tumor beyond the nasal cavity and paranasal sinuses including involvement of the cribriform plate, base of skull, orbit, or intracranial cavity
D	Tumor with metastasis to cervical lymph nodes or distant sites

all these tumor types rests on the immunohistochemical staining profile for a given tumor (see [Table 3-6](#)).

Treatment and Prognosis

- Complete surgical eradication (craniofacial resection that includes removal of the cribriform plate) followed by full course radiotherapy is the preferred treatment.
- Limited success using chemotherapeutic modalities (concurrent chemotherapy and neoadjuvant chemotherapy) achieved for advanced unresectable tumors and/or for disseminated disease
- The overall 5-, 10-, and 15-year survival rates have been reported to be 78%, 71%, and 68%, respectively:
 - More recent evidence reports a 10-year survival rate for all patients of greater than 80%.
- Five-year disease-specific and recurrence-free survival rates reported to be 83% and 64%, respectively.
- Initial multimodality therapy is associated with 5-year survival of 80% for low-grade tumors and 40% for high-grade tumors.
- The majority of the recurrences occur within the first few years (2 to 4 years) following treatment:
 - Most frequent recurrence is local, with rates around 30%.
 - Late recurrences may occur, necessitating lifelong follow-up with clinical examination and serial imaging (including neck and entire intracranial compartment).
- Prognosis has traditionally been correlated to clinical staging as defined by Kadish ([Table 3-8](#)) with:
 - 5-year survival of 75% for Stage A tumors
 - 5-year survival of 68% for Stage B tumors
 - 5-year survival of 41% for Stage C tumors
- A revision of the Kadish staging system was proposed to include metastatic tumor to cervical lymph nodes or distant sites representing Stage D ([Table 3-9](#)), a good predictor of outcome.
- Complete tumor resection was found to be of more prognostic importance than clinical staging.
- Other factors purportedly implicated in prognosis include:
 - Histologic grading:
 - Histologically lower grade tumors (grades I and II) have been reported to have a better 5-year survival than higher-grade tumors (grades III, IV).
 - Proliferation rate and ploidy:
 - High proliferation indices and high rate of ploidy/aneuploidy have been correlated with increased morbidity (i.e., tumor recurrence, metastasis) and mortality (i.e., decreased survival).
 - Intracranial extension of the disease and positive surgical margins are independent predictors of worse overall, disease-specific, and recurrence-free survival.
- Majority of tumors behave as locally aggressive lesions mainly involving adjacent structures (orbit and cranial cavity).
- Local recurrence and distant metastasis may occur years following the initial diagnosis:
 - Approximately 15% to 70% of patients will experience local recurrence.
 - 10% to 25% will have cervical lymph node metastasis.
 - Approximately 10% to 60% will experience distant metastasis.
- More common sites of metastatic disease include lymph nodes, lungs, and bone:
 - All histologic grades have the capacity to metastasize.

OLFACTORY CARCINOMA

Definition: Rare, little-described variant of ONB characterized by a histologically high-grade ONB confirmed by immunohistochemical staining admixed with foci of carcinoma in the form of squamous or glandular differentiation as seen by light microscopy

and/or diffuse immunohistochemical staining for epithelial markers.

- Origin not clarified but may originate from olfactory epithelium lining the surface of the olfactory mucosa and/or submucosal minor salivary glands present in the olfactory mucosa (i.e., Bowman's glands)
- Absence in the literature of studies detailing clinical features, treatment, and prognosis
- If confronted with a possible diagnosis of olfactory carcinoma:
 - Clinical (e.g., Kadish) staging warranted
 - Complete surgical extirpation to include tumor-free margins indicated
 - Adjuvant therapy (e.g. radiation) may be required.
 - Evaluation for presence of metastatic (nodal and visceral) disease should be undertaken.

NEUROENDOCRINE CARCINOMAS

- Neuroendocrine carcinomas (NEC) represent a heterogeneous group of malignant neoplasms with divergent differentiation along epithelial and neuroendocrine cell lines.
- For a more complete discussion of NEC see Section 5, Larynx.
- The classification of NEC is to some extent still debated:
 - Some divide these tumors into:
 - Carcinoid tumor
 - Atypical carcinoid tumor
 - Small cell carcinoma
 - Others classify them according to differentiation:
 - Well-differentiated neuroendocrine carcinoma (equated with carcinoid tumor)
 - Moderately differentiated neuroendocrine carcinoma (equated with atypical carcinoid)
 - Poorly differentiated neuroendocrine carcinoma (equated with small cell undifferentiated neuroendocrine carcinoma [SCUNC])
 - Another classification includes an admixture of the above schemes:
 - Carcinoid
 - Moderately differentiated neuroendocrine carcinoma
 - Small cell neuroendocrine carcinoma
 - More recently, the large cell variant of NEC (LCNEC) reported in the head and neck, primarily involving the larynx but also reported in other sites including the sinonasal tract; for more details see Section 5, Larynx.
 - According to the time-honored terminology and to minimize confusion, the terms carcinoid, atypical carcinoid, small cell carcinoma, and large cell carcinoma, as proposed by the World Health Organization, are used in this book, but the “atypical” carcinoid tumor is a fully lethal tumor and the term “atypical” should not lull the clinician into a false sense of security that this tumor is only slightly different in its behavior from the relatively indolent “classic” carcinoid tumor.
- Given the recent identification of the large cell neuroendocrine carcinoma of the head and neck, the classification of head and neck NEC includes:
 - Carcinoid tumor (well-differentiated neuroendocrine carcinoma)
 - Atypical carcinoid tumor (moderately differentiated neuroendocrine carcinoma)
 - Small cell (neuroendocrine) carcinoma (poorly differentiated neuroendocrine carcinoma)
 - Large cell neuroendocrine carcinoma
- In general, all subtypes of NEC are uncommon in the head and neck and even more so in the sinonasal tract.
- Most commonly encountered subtype of NEC in the head and neck is the small cell undifferentiated carcinoma (SCUNC) followed by the atypical carcinoid; carcinoid tumor and LCNEC are least common.
- NECs, especially SCUNC, may be identified in virtually all upper aerodigestive tract sites but primarily involve the larynx; less frequently, NECs occur in salivary glands (parotid) and sinonasal tract.
- SCUNC of the sinonasal tract affects men and women equally and occurs over a wide age range from the third to eighth decades of life with a mean of 49 years.
- Sinonasal tract SCUNC most commonly occurs in the superior or posterior nasal cavity, often with extension into adjacent paranasal sinuses (e.g., maxillary and ethmoid sinuses).
- Primary paranasal sinus disease in the absence of nasal cavity involvement may occur.
- Presenting signs and symptoms include nasal obstruction, epistaxis, and pain; local invasion may result in exophthalmos.
- Irrespective of the site of occurrence, the histologic appearance of SCUNC is the same:
 - Foci of squamous differentiation may be present:
 - CK5/6 and p63 positive, which are typically absent in the neuroendocrine component
 - Rhabdomyoblastic differentiation may be present:
 - Cells are desmin and myogenin positive.
- Oropharyngeal SCUNC may be associated with HPV (see Section 3, Pharynx for more complete discussion):
 - In contrast to the relatively favorable prognosis associated with HPV-associated squamous cell carcinomas of the oropharynx, the findings of the HPV-associated NEC of the oropharynx suggest an aggressive behavior despite its association with HPV.

- Differential diagnosis for NEC, especially SCUNC of the sinonasal tract, includes other “small round cell” malignant neoplasms as well as other malignancies:
 - Sinonasal undifferentiated carcinoma
 - Small cell undifferentiated neuroendocrine carcinoma
 - Nasopharyngeal-type undifferentiated carcinoma
 - Sinonasal-based lymphoepithelial carcinoma
 - Squamous cell carcinoma, keratinizing and non-keratinizing types
 - Mucosal malignant melanoma
 - Nasal-type NK/T-cell lymphoma
 - Rhabdomyosarcoma
 - Ewing sarcoma family of tumors
 - NUT midline carcinoma

NOTE: Although differences can be identified by light microscopic evaluation, often the differentiation of all these tumor types rests on the immunohistochemical staining profile for a given tumor (see Table 3-6).

- Preferred treatment for SCUNC is multimodality therapy including (neoadjuvant) chemoradiotherapy; surgery is not considered appropriate therapy due to the high rate of metastatic disease, although treatment protocols vary and some advocate incorporating radical surgery.
- SCUNCs are highly malignant tumors; median survival rates for head and neck SCUNC are reported to be 14.5 months.
- Local recurrence and distant metastasis occur frequently with reported rates of 45% and 35%, respectively.
- Metastases occur to cervical lymph nodes, lung, liver, and bone.

MUCOSAL MALIGNANT MELANOMA (MMM)

(Figs. 3-61 through 3-70)

Definition: Neural crest-derived neoplasm originating from melanocytes and demonstrating melanocytic differentiation.

Clinical

- Approximately 15% to 25% of all malignant melanomas arise in head and neck sites.
- Of the head and neck malignant melanomas more than 80% are of cutaneous origin.
- MMM of the upper aerodigestive tract represents from 0.5% to 3% of malignant melanomas of all sites:
 - Of the noncutaneous head and neck malignant melanomas, the majority are of ocular origin.
 - Most common site of the upper aerodigestive tract is the oral cavity.

- Approximately 6% to 8% originate in the mucous membranes of the upper aerodigestive tract.
- Less common sites of involvement include sinonasal tract, nasopharynx > pharynx, larynx and middle ear.
- Sinonasal tract MMM accounts for less than 5% of all sinonasal tract neoplasms.
- Irrespective of the site of occurrence, upper aerodigestive tract MMMs are more common in men than women.
- Primarily a disease of adults, occurring over a wide age range but most frequently in the sixth to eighth decades of life with a peak incidence in the seventh decade:
 - Rarely if ever occurs in infants and children
- Most examples of upper aerodigestive tract MMM occur in Caucasians, but blacks are also affected.
- Symptoms vary according to the site of occurrence:
 - Sinonasal tract and nasopharynx include airway obstruction, epistaxis, pain, nonhealing ulcer, and dysphagia
- In the sinonasal tract, nasal cavity involvement is more common than that of the paranasal sinuses:
 - In the nasal cavity, the most frequent site of occurrence is the septum (anterior portion) and the lateral nasal wall.
 - In the sinuses, the maxillary sinus is the most common site of occurrence followed by the ethmoid, frontal, and sphenoid sinuses.
 - Concurrent nasal cavity and paranasal sinus melanomas frequently occur either as a result of direct extension or as multicentric tumors.
- No known etiologic agents linked to the development of MMM, but there is consideration that tobacco smoking plays an important factor in the development of (laryngeal) MMM.

Pathology

Gross

- Variety of appearances including polypoid or sessile, brown, black, pink or white, friable to rubbery masses measuring from 1.0 cm to large, resulting in obstructive signs and symptoms

Histology

- In general, surface ulceration is a common finding:
 - In tumors with an intact surface epithelium, continuity of the tumor with the surface epithelium (junctional or pagetoid changes) can be identified.
 - Presence of a junctional or in situ component suggests origin from the surface epithelium.
 - Junctional or in situ melanoma not a requirement for a diagnosis of MMM, as melanocytes are found in the submucosa of the upper aerodigestive tract (in association with seromucous glands

Fig. 3-61. Gross appearances of mucosal malignant melanoma.

Mucosal malignant melanomas of upper aerodigestive tract include (A) the oral cavity (most common nonocular head and neck site) appearing as a discolored palatal mass; (B) nasal cavity appearing as a fleshy mass in the nasal vestibule with widening of the nasal cavity and radiographic evidence (not shown) of destructive growth; (C) nasal septum appearing as an exophytic, black mass in this resection specimen.

- or separate from seromucous glands), potentially giving rise to MMM in the absence of junctional or in situ melanoma.
- Cytomorphologic features include epithelioid or spindled cells; tumors with mixed epithelioid and spindle cells are frequently seen.
- In predominantly or exclusively epithelioid cell MMM:
 - Growth patterns vary and may be solid, organoid, nested, trabecular, alveolar, or any combination of these patterns.
 - Cells are round to oval and tend to be markedly pleomorphic, having increased nuclear-to-cytoplasmic ratio, vesicular to hyperchromatic nuclei, prominent eosinophilic nucleoli, and eosinophilic to clear-appearing cytoplasm.
 - Nuclear pseudoinclusions and nuclear molding are present.
 - Epithelioid cells may have plasmacytoid features with eccentrically located nuclei and eosinophilic cytoplasm, but in contrast to plasma cell proliferations, the nuclear chromatin pattern is more

Fig. 3-62. Sinonasal mucosal malignant melanoma.

Axial CT scan (**A**) shows an enhancing, expansile polypoid mass in the left nasal fossa. The left antrum is obstructed. There is virtually no bone destruction associated with this benign-appearing lesion. Axial CT scan (**B**) on another patient shows a primarily expansile right nasal fossa mass that obstructs the right antrum. There is a greater element of bone destruction than in **A**. Coronal CT scan (**C**) on a third patient shows a primarily destructive mass in the nasal fossae, ethmoid sinuses, and left maxillary sinus. The tumor has invaded the left orbit and the floor of the anterior cranial fossa. All of these patients had melanomas. These three cases illustrate the variation of the imaging appearance of this tumor. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 293, Fig. 4-84.)

- densely hyperchromatic and there is no paranuclear clear zone.
- In predominantly or exclusively spindle cell MMM:
 - Growth patterns may be storiform and/or fascicular.
 - Cells are oblong to cigar-shaped and markedly pleomorphic with large vesicular to hyperchromatic nuclei, absent to prominent nucleoli, and scant eosinophilic cytoplasm.
 - Spindle cell MMM may have an associated myxoid stroma:
 - Myxoid stroma may be so prominent as to suggest a myxoid type of sarcoma.
 - In both epithelioid and spindle cell MMM, necrosis (individual cell and confluent foci) and increased mitotic activity, including atypical mitoses, are common findings; uncommon features that may be seen include neoplastic giant cells and glandular or squamous differentiation.
 - By light microscopy, MMM may demonstrate heavy melanin deposition, but approximately one third of cases have only focal, weak pigmentation or are nonpigmented.
 - Histochemistry:
 - Identification of melanin by argentaffin (Fontana) and argyrophilic (Churukian-Shenk) positive staining
 - Intracytoplasmic diastase-sensitive, PAS-positive material indicative of glycogen may be present.
 - Mucicarmine negative

Fig. 3-63. Sinonasal mucosal malignant melanoma.

Axial fluorodeoxyglucose (FDG)-PET/CT scans through the upper (**A**) and mid (**B**) nasal cavity show two distinct, polypoid masses that are intensely avid. This patient had two separate mucosal melanomas. (*Som PM, Curtin HD: Head and neck imaging, ed 5, Philadelphia, 2011, Elsevier, p 295, Fig. 4-88.*)

- Immunohistochemistry:
 - Represents the gold standard for the diagnosis of malignant melanoma irrespective of cell type:
 - S100 protein and vimentin; S100 protein staining is typically diffuse and strong (nuclear and cytoplasmic).
 - HMB-45, melan-A, tyrosinase, microphthalmia transcription factor (MITF); staining is typically diffuse and strong:
 - Exceptions to staining pattern may occur in desmoplastic melanomas in which S100 protein and tyrosinase may be more sensitive than the other melanoma-related markers.
- Sox10:
 - Transcription factor involved in neural crest development and differentiation of neural crest cells into melanocytic and Schwannian differentiation
 - Sensitive marker for melanoma:
 - Diffuse and strong nuclear staining
 - Expression reported in more than 85% to 90% of melanomas
 - Reactivity also present in:
 - Schwannomas (100%)
 - Neurofibromas (greater than 90%)
 - Salivary gland neoplasms, especially those with myoepithelial differentiation

Fig. 3-64. Sinonasal mucosal malignant melanoma.

A, In most examples there is no evidence of junctional activity or evidence of premalignant intraepithelial changes either due to surface ulceration, as seen here, or due to origin from melanocytes localized in the submucosa; a diffuse invasive cellular infiltrate of epithelioid-appearing pleomorphic cells is present. **B**, Occasionally, junctional activity may be present (*left*).

- Malignant peripheral nerve sheath tumors (30% to 50%)
 - Clear cell sarcomas (approximately 60%)
 - Sustentacular cells of paragangliomas and pheochromocytoma
- c-kit expression may be present.
- Generally no immunoreactivity for cytokeratins, epithelial membrane antigen (EMA), p63, neuroendocrine markers, myogenic markers, hematolymphoid markers:
 - Rare examples of MMM reported to be reactive for epithelial markers, including CAM 5.2 (CK8/18) and EMA
- Electron microscopy:
 - Melanosomes and premelanosomes can be seen.
- Molecular genetics:
 - Serine/threonine-protein kinase B-raf (*BRAF*) mutations:
 - Present in 50% to 60% of cutaneous malignant melanoma
 - Uncommon in MMM; present in less than 20% of cases
 - c-kit:
 - Somatic mutations of c-kit with oncogenic point mutations in less than 20% of MMM
 - NRAS mutations:
 - Appear to be relatively more frequent than *BRAF* and c-kit

Intraoperative Consultation (Frozen Section) in Sinonasal MMM

- Intraoperative frozen margins for sinonasal tumors considered reliable for most histologic subtypes except for sinonasal MMM:
 - Overall false-negative rate for all tumor types by intraoperative frozen margins reported to be 6.5%
 - False-negative margin rate for MMM of 25%
 - Implications relate to size of margins required in resection of sinonasal MMM melanomas, which need to be larger than those for other tumors.

Differential Diagnosis

- Metastasis from a separate primary cutaneous or noncutaneous, non-head and neck malignant melanoma:
 - Before a diagnosis of a primary MMM of the upper aerodigestive tract is made, a metastasis from a cutaneous primary malignant melanoma or another malignant melanoma of another primary site must be excluded.
 - Cutaneous malignant melanomas are capable of spontaneous regression, lying dormant for many years only to re-emerge as a metastasis (distant from the primary cutaneous site of occurrence).

Fig. 3-65. Sinonasal epithelioid mucosal malignant melanoma.

A, The neoplastic infiltrate has a diffuse growth composed of round to oval, markedly pleomorphic cells with increased nuclear-to-cytoplasmic ratio, vesicular to hyperchromatic nuclei, nuclear molding, prominent eosinophilic nucleoli, and eosinophilic cytoplasm; scattered intracytoplasmic fine pigmentation is present consistent with melanin. **B,** In addition, intranuclear pseudoinclusions and increased mitotic activity are present. **C,** Clear cell cytoplasmic changes and **(D)** plasmacytoid-appearing cells may be focally present or represent the dominant cell type in a given case.

- Detailed clinical history to include knowledge of a prior excision (cutaneous and otherwise) is imperative; further, if available, histologic review of all appropriate previous excisions is strongly recommended.
 - In the face of a known history of a prior melanoma and/or histologic review confirming a prior diagnosis of melanoma, the sinonasal tract neoplasm can be considered as representing a metastasis.
 - In the absence of a previous or concurrent malignant melanoma elsewhere, the MMM can be considered as a primary neoplasm.
 - Presence or absence of *BRAF* mutations may have diagnostic utility in differentiating a possible metastatic cutaneous malignant melanoma (*BRAF* mutated) versus a primary sinonasal or other upper aerodigestive tract MMM (*BRAF* nonmutated).
 - Sinonasal undifferentiated carcinoma
 - Small cell undifferentiated neuroendocrine carcinoma
 - Nasopharyngeal-type undifferentiated carcinoma
 - Sinonasal-based lymphoepithelial carcinoma
 - Squamous cell carcinoma, keratinizing and nonkeratinizing types
 - Nasal-type NK/T-cell lymphoma
 - Rhabdomyosarcoma
 - Ewing sarcoma family of tumors
 - NUT midline carcinoma
- NOTE:** Although differences can be identified by light microscopic evaluation, often the differentiation of all these tumor types rests on the immunohistochemical staining profile for a given tumor (see [Table 3-6](#)).

Treatment and Prognosis

- Irrespective of their site of origin, MMMs as a group represent aggressive and highly lethal tumors.
- Radical surgical excision is the preferred treatment.

Fig. 3-66. Sinonasal mucosal malignant melanoma.

A, Admixture in a single case of epithelioid and spindle-shaped cells. **B** and **C**, Melanomas may be composed entirely of spindle-shaped cells with a fascicular to storiform growth that in the absence of light microscopic evidence of melanin may be mistaken for a sarcoma or spindle cell squamous carcinoma.

Fig. 3-67. Melanin in mucosal malignant melanomas is variable.

A, Readily identifiable intracytoplasmic melanin may be present. **B**, Not uncommonly, there may be an absence of melanin or the presence of scattered isolated cells with intracytoplasmic pigmentation suggestive of melanin. **C**, Histochemical confirmation of melanin includes (*left panel*) Fontana and (*right panel*) Churukian-Schenk staining. Melanin is present in the epithelioid cells and spindle-shaped cells in both panels.

Fig. 3-68. Immunohistochemical staining in mucosal melanoma.

Often a diagnosis of mucosal malignant melanoma requires immunohistochemical confirmation as seen by reactivity for (A) S100 protein (nuclear and cytoplasmic); (B) HMB-45 (cytoplasm); (C) MelanA (cytoplasm); (D) tyrosinase (cytoplasm); (E) MITF (nuclear); and (F) SOX10 (nuclear).

Fig. 3-69. Variant histology of melanoma.

Melanoma is notorious for being the “great masquerader,” simulating by light microscopy the appearance of other tumor types. **A** through **C**, Mucosal malignant melanoma showing a multinodular growth pattern with prominent myxoid stroma and cells with relatively uniform spindle-shaped nuclei; in **C**, scattered melanin was identified and the diagnosis was confirmed by immunohistochemical stains (not shown).

- Adjuvant radiotherapy and chemotherapy are of questionable value in the management of MMM.
- Prolonged palliation (i.e., survival) may be achieved in a limited number of patients following multimodality treatment (surgery and radiotherapy).
- Radiotherapy or chemotherapy in the treatment of MMM is felt to have little effect on local or distant disease, and presently is used as adjuvant therapy.
- Overall, the prognosis for MMM of all upper aerodigestive tract sites is considered poor:
 - 5-year survival rates generally less than 30%
- Targeted therapy:
 - Given the absence of *BRAF* mutations in the majority of MMM cases, targeted therapy used for *BRAF*-mutated cutaneous malignant melanomas is less promising for patients with MMM.
 - Presence of activated c-kit mutations raises possible utility of targeted therapy, with tyrosinase kinase inhibitors found to be effective for tumors with c-kit mutations.
- For sinonasal tract MMM, the 5-year disease-specific survival ranges from 10% to 46%; median survival of 2 years.
- There is no time period after which a patient with MMM should be considered as cured.
- Malignant melanoma is notorious for remaining quiescent for long periods following the initial diagnosis, only to resurface years to decades later.
- Recurrence, metastasis, and death may occur decades after “curative” therapy.
- Metastatic disease occurs most frequently to the lungs, lymph nodes, and brain.
- Histopathologic determination of the anatomic level of invasion (Clark level) and thickness of tumor (Breslow thickness) used for cutaneous malignant melanomas and are not applicable to MMM.

Fig. 3-70. Variant histology of melanoma.

Another example of mucosal malignant melanoma with unusual histology. **A**, Scattered nests of epithelioid cells with cytoplasmic vacuolization; intranuclear pseudoinclusions are present. **B**, *left panel*, intracytoplasmic pigment suggestive of melanin is present confirmed by *right panel* Fontana stain. **C**, The cells contain glycogen as evidence by the presence of diastase-sensitive, PAS-positive intracytoplasmic material (*left panel*, PAS; *right panel*, PAS with diastase digestion). **D**, Immunohistochemical confirmation of melanoma includes (*left panel*) S100 protein and (*right panel*) HMB45 reactivity.

MELANOTIC NEUROECTODERMAL TUMOR OF INFANCY (MNTI)

(Figs. 3-71 through 3-73)

- Rare primitive neuroectodermal tumor occurring most often in infants in the first year of life and primarily arising in head and neck sites (anterior maxilla \gg other craniofacial sites) with evidence of epithelial, neural, mesenchymal, and neuroectodermal differentiation.
- Believed to be of neural crest origin
- Synonyms include melanotic progonoma; congenital melanocarcinoma; retinal anlage tumor; melanotic adamantinoma.
- Rarely, MNTI may occur in sites other than head and neck, including:
 - Mediastinum, brain, anterior fontanelle, mandible, femur, epididymis
- Presents as a rapidly growing soft tissue mass in the area of the upper jaw (canine teeth) with or without bone destruction.
- Radiology:
 - Cystic radiolucent lesion
 - Local destruction may be identified including displacement of teeth.
- Histopathology characterized by an alveolar or pseudoglandular growth composed of a biphasic cell population consisting of:
 - Smaller cells:
 - Small round, lymphocytic-like cells with hyperchromatic nuclei and scant cytoplasm (neuroblastic cells)
 - Neurofibrillary matrix may be present.
 - Neural type rosettes absent
 - Larger cells:
 - Epithelioid cells with vesicular nuclei, prominent nucleoli and eosinophilic cytoplasm
 - Noteworthy for the presence of melanin

Fig. 3-71. Melanotic neuroectodermal tumor of infancy (MNTI).

A, Infant with a lesion of the maxilla protruding from her mouth with a red to black appearance; a tooth is identifiable. **B,** The tumor was completely excised and was oval, firm, and tan-gray to red in appearance; the tooth is seen along one edge of the resection specimen.

- Rhabdomyoblastic differentiation may be identified:
 - Myogenin-positive cells
- Immunohistochemistry:
 - Polyphenotypic expression of epithelial, neural, mesenchymal, and melanocytic cell markers:
 - Both small and large cells: expression of NSE, CD57 (Leu-7); variable reactivity for desmin and muscle specific actin
 - Smaller cell component: variable expression of synaptophysin, GFAP
 - Larger cell component: consistent expression of cytokeratin, HMB-45 and vimentin; variable EMA expression

Fig. 3-72. MNTI.

A, The tumor is infiltrative with nests of dark appearing cells separated by fibroconnective tissue. **B,** Infiltration into bone (and other soft tissue structures) may be present.

Fig. 3-73.

MNTI comprises a dual cell population, including (*left panel*) small round, lymphocytic-like cells with hyperchromatic nuclei and scant cytoplasm (neuroblastic cells) and (*right panel*) larger epithelioid cells with vesicular nuclei, eosinophilic cytoplasm, and melanin.

- No immunoreactivity in either cell component for S100 protein, neurofilament, CEA
- Cytogenetics:
 - Absence of t(11;22) translocations:
 - In the absence of this translocation MNTI is not considered to be within the same family of tumors as Ewing sarcoma and primitive neuroectodermal tumor (PNET).
- Treatment is surgical but should include tumor-free margins.
- Local recurrence is usually the result of inadequate surgical resection.
- Majority of MNTI are benign:
 - Low rate of recurrence
 - Small percentage behave in a malignant manner (metastatic disease).
- Malignant-behaving MNTI require surgery, radiation therapy, and chemotherapy:
 - Aggressive neoplasms
 - May have widespread dissemination, usually to regional lymph nodes
 - Marked decrease in survival

SINONASAL (MUCOSAL) ADENOCARCINOMA

- Adenocarcinomas of the sinonasal tract represent from 10% to 20% of all primary malignant neoplasms of this region but, exclusive of salivary gland types, represent only 6.3% of all malignant sinonasal tract tumors.
- Malignant salivary gland neoplasms are discussed later in this chapter.
- Two main categories of nonsalivary gland type adenocarcinomas are recognized in the sinonasal tract including:
 - Intestinal type adenocarcinomas
 - Nonintestinal type adenocarcinomas

Intestinal Type Adenocarcinomas (ITAC) (Figs. 3-74 through 3-78)

Definition: Malignant epithelial glandular neoplasm of the sinonasal tract that histologically resembles intestinal adenocarcinoma and adenoma.

Clinical

- More common in men than in women; occur over a wide age range but are most common in the fifth to seventh decades of life
- Most frequently involve the ethmoid sinus followed by the nasal cavity (inferior and middle turbinates) and maxillary sinus; however, may arise anywhere in the sinonasal tract

Fig. 3-74. Sinonasal tract intestinal type adenocarcinoma, papillary.

The papillary type shows a predominance of papillary architecture with minimal cytologic atypia.

- Early symptoms tend to be nonspecific and vary from nasal stuffiness to obstruction that, with persistence, may be associated with epistaxis, prompting further clinical evaluation.
- Due to the delay in diagnosis, tumors may reach a large size with extensive invasion at the time of presentation.
- Advanced tumors present with pain, cranial nerve deficits, visual disturbances, and exophthalmos.
- Etiologic factors associated with the development of ITAC include exposure to hardwood dust, leather, and softwood; increased incidences of adenocarcinoma are seen in woodworkers and workers in the shoe and furniture industries:
 - Wood dust exposure shown to be causal factor in the mutagenesis of TP53 possibly caused by reactive nitrogen species generated through a chronic inflammatory process, suggesting a role in the pathogenesis of ITAC

Fig. 3-75. Sinonasal tract intestinal type adenocarcinoma, colonic type.

The colonic type shows tubulo-glandular architecture with increased nuclear pleomorphism and mitotic activity.

Fig. 3-76. Sinonasal tract intestinal type adenocarcinoma, solid type.

The solid type shows a loss of differentiation characterized by solid growth with tubule formation, nuclear pleomorphism, round vesicular nuclei, prominent nucleoli, and increased mitotic figures.

- Significant association between COX-2 expression with occupational exposure to wood dust, suggesting a role for inflammatory components in the carcinogenesis process
- Sporadic ITAC unassociated with occupational exposure occur and tend to affect women more than men, with most tumors involving the maxillary antrum.

Pathology

Gross

- These tumors have a variable appearance; they may be well demarcated to poorly defined and invasive, flat, to exophytic or papillary growths with a tan/white to pink color and a friable to firm consistency.
- A mucinous or gelatinous quality may be readily identifiable.

Histology

- Invasive tumors with various growth patterns, including papillary-tubular, alveolar-mucoid or alveolar-goblet, signet-ring, and mixed
- Two classifications have been proposed ([Table 3-10](#))
 - Barnes classification divided ITAC into 5 categories, including:
 - Papillary
 - Colonic
 - Solid
 - Mucinous
 - Mixed
 - Kleinsasser and Schroeder classification divided ITAC into four categories, including:
 - Papillary tubular cylinder (PTCC) types I-III (I = well differentiated, II = moderately differentiated, and III = poorly differentiated)
 - Alveolar goblet type

Fig. 3-77. Sinonasal tract intestinal type adenocarcinoma, mucinous type.

A, Large, well-formed glands distended by mucus and extracellular mucin pools. **B**, Clusters of individual glands and signet ring cells. **C**, Intracellular mucin within (*left panel*) columnar cells and (*right panel*) signet ring cells; a prominent mucomyxoid matrix is present.

Fig. 3-78. Sinonasal tract intestinal type adenocarcinoma, colonic subtype.

Among the immunomarkers that these tumors are reactive for include (**A**) CD20, (**B**) CDX2, and (**C**) villin.

TABLE 3-10 Classification of Sinonasal Tract Intestinal-Type Adenocarcinoma (ITACs)

Barnes	Kleinsasser and Schroeder	Percentage of Cases	3-Year Cumulative Survival*
Papillary-type	PTCC-I	18%	82%
Colonic-type	PTCC-II	40%	54%
Solid-type	PTCC-III	20%	36%
Mucinous-type	Alveolar goblet	Uncommon	48%
	Signet-ring	Uncommon	0
Mixed	Transitional	Rare	71%

PTCC, Papillary tubular cylinder cell.

*Survival data derived from Kleinsasser and Schroeder.

- Signet-ring type
- Transitional type
- Barnes papillary, colonic, and solid types correspond to Kleinsasser and Schroeder PTCC-I, PTCC-II, and PTCC-III, respectively.
- Either classification is acceptable, but for simplicity the Barnes classification is preferred and is the one used in this section.
- Most common histologic types seen in association with woodworkers as well as in sporadically occurring cases are the papillary and colonic types.
- Papillary type (papillary tubular cylinder I or well-differentiated adenocarcinoma), representing approximately 18% of cases, shows a predominance of papillary architecture with occasional tubular glands, minimal cytologic atypia, and rare mitotic figures.
- Colonic type (papillary tubular cylinder II or moderately differentiated adenocarcinoma) shows a prevalence of tubuloglandular architecture, rare papillae, with increased nuclear pleomorphism and mitotic activity.
- Solid type (papillary tubular cylinder III or poorly-differentiated adenocarcinoma) shows a loss of differentiation characterized by solid and trabecular growth with isolated tubule formation, marked increased in the number of smaller cuboidal cells with nuclear pleomorphism, round vesicular nuclei, prominent nucleoli, and increased mitotic figures.
- Analogous to colonic adenocarcinoma, some ITAC are predominantly composed of abundant mucus production and are classified as mucinous type of ITAC.
- Mucinous type (alveolar goblet cell and signet ring) includes two growth patterns:
 - In one pattern there are solid clusters of cells, individual glands, signet ring cells, short papillary fronds with or without fibrovascular cores; mucin

is predominantly intracellular and a mucomyxoid matrix may be present.

- The other pattern shows the presence of large, well-formed glands distended by mucus and extracellular mucin pools; pools of extracellular mucin are separated by thin connective tissue septa, creating an alveolar type pattern.
- Predominantly cuboidal or goblet tumor cells are present in single layers at the periphery of mucus lakes.
- Mucus extravasation may elicit an inflammatory response that may include multinucleated giant cells.
- Tumors in which the mucus component predominates (>50%), similar to their gastrointestinal counterparts, may be classified as mucinous adenocarcinomas.
- Mixed type (transitional) is composed of an admixture of two or more of the previously defined patterns.
- Irrespective of the histologic type, ITAC histologically simulate normal intestinal mucosa and may include villi, Paneth cells, enterochromaffin cells, and muscularis mucosa.
- In rare instances, the lesion is composed of well-formed villi lined by columnar cells resembling the absorptive cells; in such cases, bundles of smooth muscle cells resembling muscularis mucosae may also be identified under the villi.
- Histochemistry:
 - Stains for epithelial mucins are positive, including intracytoplasmic and extracellular mucicarminophilia.
- Immunohistochemistry:
 - Diffusely positive for epithelial markers including epithelial membrane antigen, B72.3, Ber-EP4, BRST-1, CD57 (Leu-M1), and human milk fat globule (HMFG-2)
 - Strongly reactive with anti-cytokeratin cocktails
 - CEA staining is variable with conflicting results in the literature, including some cases with diffuse staining, some cases with focal staining, and some cases with no staining.
 - CK20 positivity (73% to 86%) and variably CK7 reactivity (43% to 93% of cases)
 - CDX-2, a nuclear transcription factor involved in the differentiation of intestinal epithelial cells and diffusely expressed in intestinal adenocarcinomas, can be found in ITAC.
 - CDX-2 reactivity not limited to ITACs but can also be seen in sinonasal nonintestinal-type neoplasms, including:
 - Sinonasal undifferentiated carcinomas, squamous cell carcinomas (keratinizing and non-keratinizing), salivary-type adenocarcinomas, and small cell carcinoma

- Nonintestinal types of sinonasal tumors are generally CK20 negative.
- CDX-2 and CK20 are highly sensitive sinonasal ITAC, but CK20 is more specific.
- Clear-cut glandular differentiation and CK20 reactivity represent more reliable features for ITACs than CDX-2 staining.
- Expression of villin and MUC2 also present
- Absence of myoepithelial-related markers including p63 and calponin; however, p63 reactivity may be present and does not exclude a diagnosis of adenocarcinoma; in such cases complexity of growth, cytomorphology and/or invasion assist in diagnosis of adenocarcinoma.
- Neoplastic cells may express a variety of hormone peptides, including serotonin, cholecystokinin, gastrin, somatostatin, and leu-enkephalin.
- Chromogranin and synaptophysin-positive cells can be identified.
- Aberrant expression of p53 and p16 commonly present:
 - p53 overexpression less frequent in mucinous subtype
- Cytogenetics and molecular genetics:
 - *k-ras* mutations in up to 25%
 - *h-ras* mutations variably identified present in some studies and absent in other studies
 - Absence of microsatellite instability by PCR
 - CGH analyses have shown a variety of gains and losses.

Differential Diagnosis

- Metastatic adenocarcinoma of gastrointestinal origin:
 - Rare occurrence to the sinonasal tract
 - Clinical history is critical in establishing a diagnosis of ITAC and in excluding a metastasis to the sinonasal tract from a gastrointestinal tract primary neoplasm.
 - Histology, histochemistry, and immunohistochemistry of ITAC and GIT adenocarcinomas are identical.
- Nonintestinal, nonsalivary gland adenocarcinoma:
- Salivary gland-type adenocarcinoma
- Nasopharyngeal low-grade papillary adenocarcinoma
- Papillary sinusitis (see Fig. 2-6, E, F):
 - In limited biopsy material including only superficial tissue fragments showing a papillary epithelial proliferation, differentiation of florid reactive chronic sinusitis with papillary architecture can present diagnostic challenges in differentiation from a papillary type of ITAC:
 - Presence of immunohistochemical staining for CDX2, CK20, villin assists in identifying papillary type of ITAC and differentiating it from papillary sinusitis.
- Sinonasal hamartomas

Treatment and Prognosis

- Treatment includes complete surgical excision, generally via a lateral rhinotomy; depending on the extent and histology of the neoplasm the surgery varies from local excision to more radical procedures (maxillectomy, ethmoidectomy, and additional exenterations).
- Radiotherapy may be used for extensive disease or for higher grade neoplasms.
- All sinonasal intestinal-type adenocarcinomas are considered as potentially aggressive, lethal tumors.
- Metastasis to cervical lymph nodes and spread to distant sites are infrequent, occurring in about 10% and 20%, respectively.
- 5-year cumulative survival rate is around 40%, with most deaths occurring within 3 years.
- Death results from uncontrollable local or regional disease with extension and invasion of vital structures and/or metastatic disease.
- Sinonasal ITAC are generally locally aggressive tumors with frequent local failure (about 50%):
 - Because most patients present with advanced local disease, clinical staging generally has no relevant prognostic significance.
- Histologic subtype has been identified as indicative of clinical behavior, with the papillary type (grade I) lesions behaving more indolently than the other variants (see Table 3-10).
- Slight differences in survival noted between ITAC occurring in occupational-exposed individuals and sporadically occurring ITAC:
 - Occupational-associated ITAC: 50% 5-year survival
 - Sporadic occurring ITAC: 20% to 40% 5-year survival

Nonintestinal (Nonsalivary Gland) Adenocarcinomas (Figs. 3-79 and 3-80)

Definition: Those sinonasal tract tumors that do not demonstrate histopathologic features of the sinonasal “intestinal” types of adenocarcinoma and are not salivary gland neoplasms.

- These adenocarcinomas are divided into low- and high-grade types.

Clinical

Low-grade

- Predominantly occur in adults but have been identified over a wide age range from 9 to 80 years:
 - Slight male predominance; wide age range from 9 to 75 years, with most occurring in fifth to

Fig. 3-79. Sinonasal tract nonsalivary, nonintestinal type adenocarcinoma, low grade.

A, Submucosal unencapsulated invasive tumor with complex glandular and papillary growth. **B**, Numerous uniform small glands or acini are present with a back-to-back growth pattern, absence of intervening stroma; the glands are lined by a single layer of nonciliated, cuboidal to columnar cells with uniform, round nuclei, mild pleomorphism, and absence of mitotic figures. **C**, Another example showing complex back-to-back growth with cells showing moderate nuclear pleomorphism, prominent nucleoli, and a mitotic figure; other types of low-grade nonsalivary and nonintestinal types of adenocarcinoma can include (**D**) clear cells and (**E**) oncocytic cells.

Fig. 3-80. Sinonasal tract nonsalivary, nonintestinal type adenocarcinoma, high grade.

A, The neoplasm invades into bone and shows solid and complex (back-to-back) glandular growth patterns. **B,** At higher magnification glandular differentiation is evident, but the neoplasm is characterized by the presence of cells with moderate to marked nuclear pleomorphism and increased mitotic activity.

seventh decades of life and average age at presentation of 53 years.

- Predilect to the ethmoid sinus (to a lesser extent as compared with the “intestinal” type) followed by nasal cavity > nasal septum > sinuses (multiple) > maxillary antrum
- Primarily present with nasal obstruction and epistaxis; pain is an infrequent feature (less than 10%).
- Duration of symptoms ranges from 2 months to 5 years with a median duration of 5.5 months
- No known etiologic factors such as tobacco, alcohol, occupational, environmental, or genetic

- Some cases reported to be associated with respiratory epithelial adenomatoid hamartoma (REAH), prompting suggestion that REAHs are precursor lesions for a subset of sinonasal low-grade adenocarcinomas.

High-grade

- Male predilection; mean age at presentation of 59 years
- Predilect to the maxillary sinus
- Primary presenting symptoms include nasal obstruction, epistaxis, pain, and facial deformity (e.g., proptosis); the duration of symptoms ranges from 2 weeks to 5 years with a median duration of 2.5 months.
- No known etiologic factors such as tobacco, alcohol, occupational, environmental, or genetic
- May occur in association with Schneiderian papilloma
- Rarely reported in association with high-risk HPV
- Both low- and high-grade types may also originate in the nasal cavity, other paranasal sinuses, or (not infrequently) in multiple sinonasal sites in various combinations.

Pathology

Gross

- These tumors have a variable appearance, including well-demarcated to poorly defined and invasive, flat to exophytic, or papillary growths with a tan/white to pink color and a friable to firm consistency.

Histology

- Either low- or high-grade, may be seen entirely within the submucosa without surface involvement or may involve the overlying ciliated respiratory epithelium

Low-grade

- Glandular or papillary growth and may be circumscribed but are unencapsulated tumors
- Numerous uniform small glands or acini are seen, often with a back-to-back growth pattern without an intervening stroma; occasionally, large, irregular cystic spaces can be seen.
- Glands are lined by a single layer of nonciliated, cuboidal to columnar cells with uniform, round nuclei, which may be limited to the basal aspect of the cell or may demonstrate stratification with loss of nuclear polarity and an eosinophilic cytoplasm.
- Cellular pleomorphism is mild to moderate and occasional mitotic figures are seen, but atypical mitoses and necrosis are absent.
- Despite the relatively bland histology, the complexity of growth, absence of two cell layers, absence of

encapsulation, and presence of invasion into the submucosa confer a diagnosis of adenocarcinoma.

- Variants include papillary, tubulopapillary, clear cell, and oncocytic adenocarcinomas.
- Multiple morphologic patterns may be seen in any one neoplasm.
- Squamous metaplasia not infrequently seen

High-grade

- Invasive tumors predominantly with a solid growth pattern, but glandular and papillary growth patterns can also be seen.
- Characterized by the presence of moderate to marked cellular pleomorphism, increased mitotic activity, including atypical forms, and necrosis
- Immunohistochemistry (both low- and high-grade):
 - Consistently and intensely CK7 reactive
 - Nonreactive for CK20, CDX2, villin, chromogranin, or synaptophysin
 - Myoepithelial-related markers, including p63, calponin, smooth muscle actin, usually (but not always) absent
- S100 protein may be positive.

Differential Diagnosis

- Low-grade adenocarcinoma:
 - Intestinal-type adenocarcinomas:
 - Presence of CK20, CDX2, and villin allow for differentiation.
 - Salivary gland-type adenocarcinomas
 - Papillary sinusitis:
 - In limited biopsy material including only superficial tissue fragments showing a papillary epithelial proliferation, differentiation of florid reactive chronic sinusitis with papillary architecture from low-grade adenocarcinoma with papillary architecture can be virtually impossible:
 - Immunohistochemical staining will not assist in differentiating florid papillary sinusitis from low-grade adenocarcinoma with papillary architecture
 - In a scenario in which limited tissue sampling precludes a definitive diagnosis, a diagnosis of “papillary glandular epithelial proliferation, not further specified” is merited with:
 - Indication that the differential diagnosis includes florid papillary sinusitis versus low-grade adenocarcinoma
 - Recommendation for additional biopsies to include deeper aspects of the lesion or conservative but complete excision to allow for differentiating these lesion types
 - Differentiation is predicated on presence of back-to-back glands, single cell type and infiltrative growth seen in low-grade adenocarcinomas versus absence of complex growth pattern,

presence of two cell layers, and absence of infiltrative growth in papillary sinusitis.

- Sinonasal hamartomas, in particular seromucinous hamartoma
- Nasopharyngeal low-grade papillary adenocarcinoma
- Metastatic adenocarcinoma from gastrointestinal tract, lung, breast, other
- For high-grade adenocarcinoma:
 - Intestinal-type adenocarcinomas
 - Salivary gland-type adenocarcinoma, including salivary duct carcinoma:
 - Androgen receptor reactivity is seen in salivary duct carcinoma but should be absent in sinonasal high-grade adenocarcinoma.
 - Nasopharyngeal low-grade papillary adenocarcinoma
 - Metastatic adenocarcinoma from gastrointestinal tract, lung, breast, other

Treatment and Prognosis

- Treatment for all the histologic variants of nonintestinal, nonsalivary gland sinonasal adenocarcinomas is complete surgical excision generally via a lateral rhinotomy:
 - Depending on the extent and histology of the neoplasm the surgery varies from local excision to more radical procedures (maxillectomy, ethmoidectomy, and additional exenterations).
- Radiotherapy may be used for extensive disease or for higher grade neoplasms.
- Chemotherapy may be used in high-grade adenocarcinomas.
- Low-grade adenocarcinoma:
 - Excellent prognosis
 - 3-year survival rates of 70% to 89%
 - May recur in up to 30% of patients
 - Low metastatic rate
 - Death due to disease is rare, occurring in less than 5% of cases, and is due to uncontrollable local invasion.
- High-grade adenocarcinoma:
 - Dismal prognosis with approximately 20% 3-year survival rates

MALIGNANT SALIVARY GLAND NEOPLASMS

- Most common malignant salivary gland tumor of the sinonasal tract (and nasopharynx) is the adenoid cystic carcinoma.
- More common malignant neoplasms of major salivary glands, including mucoepidermoid carcinoma and acinic cell adenocarcinoma, are uncommon in the sinonasal tract (and nasopharynx):

- Most acinic cell adenocarcinomas arising outside the parotid gland including the sinonasal tract (and nasopharynx) more likely represent mammary analogue secretory carcinoma.
- For a more detailed discussion see Section 6, Salivary Glands.

Sinonasal Adenoid Cystic Carcinoma

- Adenoid cystic carcinoma (AdCC) is a malignant salivary gland neoplasm characterized by a distinctive histologic appearance, a tendency to invade nerves, and its protracted but nonetheless relentless clinical course.
- Approximately 20% of all AdCCs occur in the sinonasal tract; AdCCs represent approximately 5% of sinonasal malignancies.
- Most common site of involvement is the maxillary sinus (57%) followed by the nasal cavity (24%), ethmoid sinus (14%), and other sites (5%).
- AdCC of the sinonasal tract is a tumor of adults and rarely occurs in the first two decades of life.
- Symptoms may include airway obstruction, epistaxis, and pain.
- Can attain large sizes with extensive infiltrative growth at presentation
- Grossly, may appear circumscribed, solid, rubbery to firm, tan-white to gray-pink mass measuring from 2 to 4 cm in greatest dimension.
- Histologic appearance is identical to AdCC of more common sites; in the sinonasal tract AdCC:
 - Is a submucosal-based, unencapsulated, infiltrating neoplasm
 - Shows varied architecture consisting of cribriform, tubular/ductular, and solid patterns
 - Individual neoplasms may have a single growth pattern, but characteristically they show multiple patterns, any one of which may predominate.
 - Most common pattern is the cribriform type, considered the “classic” pattern, demonstrating arrangement of cells in a “Swiss cheese” configuration with many oval or circular spaces; these spaces contain basophilic mucinous substance or hyalinized eosinophilic material.
 - Tubular type has cells arranged in ducts or tubules; the ducts or tubules contain faintly eosinophilic mucinous material.
 - Cribriform and tubular patterns often occur together.
 - The least common pattern is the solid type, composed of neoplastic cells arranged in sheets or nests of varying size and shape with little tendency to form cystic spaces, tubules, or ducts.
- Irrespective of the growth pattern, the tumors are composed of a combination of abluminal-type myoepithelial cells (the predominant cell) and duct-lining cells.
- In the solid pattern, the cell population is dominated by the basaloid myoepithelial cells.
- Cellular and nuclear pleomorphism, necrosis, and mitotic activity are limited in the cribriform and tubular patterns; these features are more frequently seen in the solid pattern.
- Common to all histologic variants is the proclivity for nerve invasion (neurotropism), including peri- and intraneural invasion; invasion of adjacent soft tissue structures, including skeletal muscle and bone, can also be seen.
- Unlike the HPV-associated carcinoma with adenoid cystic-like features (see previously in this chapter), sinonasal AdCCs:
 - Show expression of the *MYB-NFIB* fusion biomarker
 - Lack intraepithelial dysplasia of the surface epithelium
 - May show p16 immunoreactivity but lack presence of transcriptionally active virus
- Preferred treatment for sinonasal AdCC is wide local excision and postoperative radiotherapy.
- Problems in the surgical removal relate to the infiltrative nature of these neoplasms with their tendency to extend along nerve segments, which is further compounded by their deceptively circumscribed macroscopic appearance.
- Recurrence rates are high, ranging from 75% to 90% and directly related to inadequate surgical excision.
- AdCCs are radiosensitive and radiotherapy is particularly useful in controlling microscopic disease after initial surgery, in treating locally recurrent disease, or as palliation in unresectable tumors.
- Radiotherapy is not curative.
- Sinonasal (and nasopharyngeal) AdCCs have similar biologic behavior to AdCCs at other locations:
 - Short-term prognosis is generally good because tumor growth is slow, but the long-term prognosis is poor.
 - 5-year survival rate (for all head and neck sites) of 75%
 - 20-year survival rate (for all head and neck sites) of 13%
 - Tumor location affects prognosis:
 - AdCCs located in major salivary glands have a better prognosis than their minor salivary gland counterparts.
 - Clinical staging plays a more decisive role than histologic grading in predicting prognosis in AdCC.

NON-HODGKIN LYMPHOMAS OF THE SINONASAL TRACT (NHL-SNT)

Definition: Heterogeneous group of hematolymphoid malignancies in which the bulk of disease is within the sinonasal tract.

- NHL-SNT include lymphomas of B-cell lineage, T-cell lineage, and NK/T-cell lineage.
- Nasal cavity lymphomas are predominantly of NK/T-cell type.
- Majority of B-cell lymphomas occur in the paranasal sinuses:
 - Diffuse large B-cell lymphoma (DLBCL) is the most common type.
 - Less often, other B-cell lymphomas of these sites occur, including Burkitt lymphoma, extranodal marginal B-cell lymphoma of the MALT type, and follicular lymphoma.

Clinical

- NHL-SNT are uncommon and account for only 1.5% of non-Hodgkin malignant lymphomas in the United States:
 - Incidence has been reported to be higher, however, in Asian and South American countries, where the incidence of primary non-Hodgkin malignant lymphoma is approximately 6.7% and 8.0% of all malignant lymphomas.
- Virtually the entire spectrum of morphologic types of lymphoma can be seen.
- Most common type of lymphoma in the sinonasal tract is the extranodal NK/T-cell lymphoma of nasal type.

EXTRANODAL NK/T-CELL LYMPHOMA, NASAL TYPE (Figs. 3-81 through 3-86)

Synonyms: Angiocentric NK/T-cell lymphoma of nasal type; angiocentric lymphoma; angiocentric immunoproliferative lesions; peripheral T-cell lymphoma; polymorphic reticulosis; lethal midline granuloma; midline malignant reticulosis; idiopathic midline destructive disease; Stewart's granuloma.

NOTE: Some of these terms have been used over the years synonymously with NHL-SNT; this is categorically incorrect. Non-neoplastic lesions, inflammatory and infectious diseases, as well as numerous benign and malignant neoplasms of the sinonasal tract may result in a destructive process occurring in the midline aspect of this region. Therefore idiopathic midline destructive

disease is not a specific term and should never be used to indicate a diagnosis of a malignant lymphoproliferative neoplasm.

Clinical

- Primarily affects men; disease of adults with a median age in the sixth decade of life
- Most common in Asians and reported with significant frequency in South and Central America and Mexico:
 - In these populations, the disease is seen primarily in individuals of Native American origin.
 - These findings suggest a racial predisposition for the disease.
 - Although uncommon, NK/T-cell lymphomas, nasal type also occur in Western populations and can affect Caucasians.
- Commonly presents as a destructive process of the midfacial region with nasal septal destruction, palatal destruction/perforation, orbital swelling, or with obstructive symptoms related to a mass:
 - A small percentage of cases present with hemophagocytic syndrome with pancytopenia.
- Irrespective of ethnic background, strongly associated with EBV.
- Rarely, patients are iatrogenically immunosuppressed transplant recipients.
- Primary lymph node involvement is extremely uncommon.
- Antineutrophil cytoplasmic antibodies (ANCA) and proteinase 3 (PR3) levels not elevated

Pathology

Gross

- No specific findings; tissue fragments often friable, hemorrhagic, and/or necrotic

Histology

- Sinonasal mucosa often with surface ulceration with associated fibrinoid necrosis, and acute and chronic inflammation:
 - Intact surface mucosa may show squamous metaplasia with or without pseudoepitheliomatous hyperplasia.
- Broad cytologic spectrum is present:
 - Usually cytologically atypical cells are present:
 - Atypical cells may vary from small and medium-sized cells to large, hyperchromatic cells.
 - Atypical cells may have irregular and elongated nuclei, prominent nucleoli, or clear cytoplasm.
 - Increased mitotic activity is often seen.
 - Epitheliotropism may be present.

Fig. 3-81. Extranodal NK/T-cell lymphoma, nasal type.

The clinical picture may include (A) sinonasal, upper lip, and orbital swelling; (B) destruction of the nasal septum with passage of a string between nasal passages. C, Same patient as in B showing not only septal destruction but also palate erosion as evidenced by the ability to pass the string between the nasal cavity and oral cavity. D, Ulcerative palatal lesion with purulent exudates due to a destructive lesion that originated in the floor of the maxillary sinus.

Fig. 3-82. Extranodal NK/T-cell lymphoma, nasal type.

At low magnification areas of geographic necrosis similar to that seen in granulomatosis with polyangiitis (formerly, Wegener granulomatosis) are present.

- In some cases overtly atypical or malignant cells are not evident:
 - Infiltrate has the appearance of a mixed (benign) inflammatory cell proliferation.
 - Presence of EBV would confirm a diagnosis even in the absence of overtly malignant cells; see below.
- An associated prominent admixed inflammatory cell infiltrate may be present:
 - Polymorphous cell population may obscure the atypical cells, causing diagnostic difficulties.
 - Benign inflammatory cell infiltrate may include mature plasma cells, histiocytes, and eosinophils.
 - Multinucleated giant cells and true granulomas are absent.
- In adequately sampled material, low-power appearance includes the presence of geographic (ischemic-type) necrosis characterized by bluish or so-called “gritty” necrosis:
 - Necrosis is a virtually constant (but not pathognomonic) feature.
 - Zonal pattern of distribution suggests a vascular pathogenesis.
 - Atypical cells invade and destroy blood vessels.
 - Vascular invasion and destruction is responsible for the designation “angiocentric lymphomas.”
 - Angiocentricity is defined as the presence of tumor cells around and within vascular spaces with infiltration and destruction of the vessel wall.
 - Perivascular localization is not sufficient for the designation of angiocentricity.
- Histochemistry:
 - Stains for microorganisms are negative.
- Immunohistochemistry:
 - NK-cell immunophenotype is most commonly present, including:
 - Cytoplasmic CD3 positive but surface (membranous) CD3 (by flow cytometry) negative
 - CD2 positive
 - CD56 (neural cell adhesion molecule [NCAM]) positive
 - Markers of cytotoxic granules are positive, including expression of:
 - Granzyme B
 - Cytotoxic granule-associated TIA-1
 - Perforin
 - T-cell markers, including CD43 and CD45RO (UCHL1), are positive.
 - CD4, CD5, CD8, CD20, CD57 (Leu-7) are negative.
 - Some cases may be CD30 positive.
 - p63 usually negative but may be focally positive.
 - T-cell receptor (TCR) and immunoglobulin (Ig) genes are germline (NK lineage):
 - T lineage cases have clonally arranged TCR genes and may express surface CD3.
 - Epstein-Barr virus:
 - Detected in most neoplastic cells in virtually all cases by in situ hybridization for EBER
 - Some cases may express EBV latent membrane protein (LMP).
 - LMP less sensitive than EBER in detecting EBV
 - Tumors that are CD56 negative may still be classified as NK/T-cell lymphomas if they express T-cell markers and cytotoxic markers and are EBV positive.
- Cytogenetics and molecular genetics:
 - NK/T-cell lymphomas are positive for EBV in greater than 95% of cases by in situ hybridization (ISH) for EBER.
 - Because EBV-positive cells are typically absent in the nasal cavity mucosa or in inflammatory diseases of the nasal cavity, the presence of EBV

Fig. 3-83. Extranodal NK/T-cell lymphoma, nasal type.

A through **D**, Diffuse dyscohesive cellular proliferation varying from small and medium-sized cells to large cells with round to oval to irregular and elongated nuclei, vesicular to hyperchromatic nuclei, prominent nucleoli, and indistinct eosinophilic to clear cytoplasm; increased mitotic activity can be seen. **E**, Occasionally a collagenized stroma may be present.

F, Tumor infiltration of sinonasal bone

by ISH can be used in conjunction with light microscopy in the diagnosis of nasal cavity NK/T-cell lymphomas:

- Identification of EBV would confer a diagnosis of NK/T-cell lymphoma, nasal type

even in cases without overtly atypical/malignant appearing cells.

- EBV virus may induce the expression of cytokines (e.g., TNF α), which could lead to the presence of necrosis; this may then represent

Fig. 3-84. Extranodal NK/T-cell lymphoma, nasal type.

A dense mixed inflammatory cell infiltrate can be seen in association with and at times obscuring the neoplastic cells and includes (A) mature lymphocytes and plasma cells and (B) eosinophils.

Fig. 3-85. Angiocentricity in extranodal NK/T-cell lymphoma, nasal type.

A, The neoplastic cells surround and invade vascular spaces (angiocentric and angioinvasion). B, Elastic stains shows disruption of the elastic membranes with tumor invasion through the wall with plugging of the vessel lumen.

the pathogenesis for the observed necrosis in those cases without vascular invasion:

- Similar phenomenon can be seen in benign and malignant EBV-positive lymphoproliferative disorders, including infectious mononucleosis, post-transplant lymphoproliferative disorders, and lymphomatoid granulomatosis.
- Immunoglobulin heavy and light chain genes typically not rearranged
- Cytogenetic abnormalities include:
 - p53 mutations from 24% to 63% of cases:
 - Suggests p53 may play a role in the pathogenesis
 - β -catenin mutations in approximately 20% of cases

- *c-kit* and *K-ras* mutations may be identified in a smaller percentage of cases.
- *FAS* mutations are a frequent finding in NK/T-cell lymphomas (50% to 60%) and may account for the presence of necrosis.
- Variety of DNA losses and gains at various loci

Differential Diagnosis

- Infectious diseases (e.g., mucormycosis, aspergillosis)
- Granulomatosis with polyangiitis (GPA) (formerly Wegener granulomatosis) (Table 3-11)
- Mucosal malignant melanoma
- Small cell neuroendocrine undifferentiated carcinoma
- Sinonasal undifferentiated carcinoma

Fig. 3-86. Immunohistochemical staining in extranodal NK/T-cell lymphoma, nasal type.

Lesional cells are immunoreactive for (A) CD3 (cytoplasmic); (B) CD56 (natural killer cell marker); (C) cytotoxic granule-associated TIA-1; and (D) in situ hybridization for EBV-encoded RNA (EBER); (E) scattered neoplastic cells show p63 reactivity.

TABLE 3-11 Clinicopathologic Comparison Between Sinonasal Malignant Lymphomas, Granulomatosis and Polyangiitis (GPA), and Allergic Granulomatosis and Vasculitis*

	Extranodal NK/T- Cell Lymphoma, Nasal Type	DLCBL	GPA	Allergic Granulomatosis and Vasculitis*
Gender/age	M > F; sixth decade; most common in Asians; occurs in Western population but with less frequency	M > F; seventh decade	M > F; fourth-fifth decades; laryngeal GPA affects F > M	M > F; wide age range (third-sixth decades)
Location	Generally limited to the sinonasal region; extra-sinonasal occurs and represents a higher stage tumor	Nasal cavity and one or more paranasal sinuses	Localized UADT GPA most common in nasal cavity > paranasal sinuses; other sites may include nasopharynx, larynx (subglottis), oral cavity, trachea, ear, salivary glands	Multisystem disease including pulmonary, nasal, renal, cutaneous, cardiac, and nervous system involvement
Symptoms	Destructive process of midfacial region: nasal septal perforation, obstruction, palate destruction, orbital swelling	Nonhealing ulcer, epistaxis, facial swelling, pain, cranial nerve manifestations	SNT: sinusitis, with or without purulent rhinorrhea, obstruction, pain, epistaxis, anosmia, headaches Larynx: dyspnea, hoarseness, voice changes Oral: ulcerative lesion Ear: hearing loss, pain	Asthma, allergic rhinitis, evidence of eosinophilia, serum and tissue (e.g., eosinophilic pneumonia, eosinophilic gastroenteritis, other), evidence of vasculitis
Systemic involvement	Majority are localized (stage IE/II/E); may progress to disseminated/systemic involvement	Majority are localized (stage IE/II/E); may progress to disseminated/systemic involvement	ELK Classification: E: ear, nose, throat L: lung K: kidney E, EL = limited form WG ELK = systemic WG	Typically patients have multisystem involvement although limited forms of disease exist
Serology	ANCA and PR3 negative; no specific serologic marker(s)	ANCA and PR3 negative; no specific serologic marker(s)	ANCA positive and PR3: • Increased in primary disease and recurrent disease • c-ANCA more specific than p-ANCA	ANCA and PR3 levels may or may not be present; peripheral eosinophilia
Histology	Overtly malignant cellular infiltrate but in early phases malignant cells may not be overtly identifiable; angiocentricity and angioinvasion; ischemic-type necrosis; no giant cells or granulomas; negative cultures and stains for organisms	Diffuse dyscohesive cellular proliferation of medium to large cells with large round to oval vesicular (noncleaved) nuclei, prominent nucleoli, increased mitotic activity, and necrosis	Polymorphous (benign) cellular infiltrate; vasculitis; ischemic-type necrosis; isolated multinucleated giant cells (not well-formed granulomas); negative cultures and stains for organisms	Polymorphous (benign) cellular infiltrate, predominantly eosinophils; vasculitis that may be a granulomatous vasculitis (multinucleated giant cells in the wall of involved blood vessels); eosinophilic microabscesses; negative cultures and stains for organisms
IHC	CD3 cytoplasmic, CD2, CD56 positive; T cell markers (CD3, others) positive; cytotoxic granule markers (granzyme B, TIA-1, perforin) positive	LCA and B-cell markers (CD20, CD79) positive; p63 may positive (focal to diffuse)	LCA, B- and T-cell markers, kappa and lambda light chains	LCA, B- and T-cell markers
EBV	Strong association	No to weak association	Negative	Negative
Treatment	Radiotherapy for localized disease; chemotherapy for disseminated disease	Radiotherapy and/or chemotherapy	Cyclophosphamide and prednisone	Systemic corticosteroids
Prognosis	5-year survival for Stage I lesions approximately 50%; local recurrence/relapse and systemic failure common	Dependent on stage; 5-year survival rates vary in the literature from 29% to 80%	Limited disease associated with a good to excellent prognosis and occasional spontaneous remissions; mortality related to complications of renal and pulmonary involvement	62% 5-year survival; increased morbidity and mortality due to cardiac involvement resulting in CHF or MI

ANCA, Antineutrophil cytoplasmic antibodies; CHF, congestive heart failure; DLCBL, diffuse large cell B-cell lymphoma; EBV, Epstein-Barr virus; GPA, granulomatosis and polyangiitis (formerly Wegener granulomatosis); IHC, immunohistochemistry; LCA, leucocyte common antigen; MI, myocardial infarction; PR3, proteinase 3; UADT, upper aerodigestive tract.

*Also known as Churg-Strauss syndrome.

- Rhabdomyosarcoma
- Ewing sarcoma family of tumors

NOTE: Although differences can be identified by light microscopic evaluation, often the differentiation of all these tumor types rests on the immunohistochemical staining profile for a given tumor (see [Table 3-6](#)).

Treatment and Prognosis

- Treatment varies depending on the extent of disease.
 - Radiotherapy for localized disease
 - Aggressive chemotherapy in disseminated disease
- Radiosensitive tumors, but prognosis is generally poor once dissemination occurs.
- Majority are localized at presentation (Ann Arbor Stage IE/IIIE):
 - Treated by radiation alone or chemoradiation
- In some patients, surgical resection may be needed for symptomatic relief (e.g., airway obstruction).
- 5-year survival of 46%
- Median survival was 4.2 years
- Local recurrence/relapse and systemic failure is common.
- Systemic failure includes increased risk of dissemination to skin, testes, and GI tract.
- Favorable prognostic factors include:
 - Limited local invasion, low international prognostic index score ([Table 3-12](#)), lack of B symptoms, low proliferation indices (as determined by Ki67 [MIB1]), lower EBV viral load in tumor tissue, lower serum EBV DNA
- Adverse prognostic factors include:
 - Extensive local invasion (to skin, bone), advanced stage disease, poor performance score (Eastern Cooperative Oncology Group [ECOG] of 2 or higher), B symptoms, regional lymphadenopathy, bulky disease, high lactate dehydrogenase level, high proliferation rate
 - Development of hemophagocytic syndrome, an uncommon complication seen in approximately 10% of cases, is considered fatal.

TABLE 3-12 International Prognostic Index Scoring System

Prognostic Factors (1 point each)				
Age > 60 years				
Elevated serum lactate dehydrogenase				
Poor performance status				
High stage (III-IV)				
>1 extranodal site				
Risk Score				
0	1	2	3	4 5
Low	Low-intermediate	High-intermediate	High	

SINONASAL DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL) (Fig. 3-87)

Definition: Diffuse proliferation of large or medium-sized neoplastic B-cells with a nuclear size greater than or equal to that of a histiocyte or more than twice the size of a small lymphocyte.

- Primarily affects men with a median age in the seventh decade of life
- Clinical presentations may include aggressive signs and symptoms, including:
 - Nonhealing ulcer, cranial nerve manifestations, facial swelling, epistaxis, or pain
 - High-grade B-cell lymphomas tend to present with soft tissue and osseous destruction and may invade into the orbit and brain, resulting in:
 - Proptosis, diplopia, decreased visual acuity, neurologic abnormalities
 - Low-grade lymphomas may present as a nasal cavity or paranasal sinus mass associated with airway obstructive symptoms.
- Sites of involvement may be one or more paranasal sinuses, or multiple regions within the sinonasal tract:
 - Maxillary sinus > ethmoid sinus, sphenoid sinus, frontal sinus
- Most arise de novo:
 - Some may transform from an underlying low-grade lymphoma.
 - Uncommon (less than 10%) to no association with EBV
- Increased risk associated with immunosuppression, including post-transplantation and human immunodeficiency virus (HIV) infection:
 - Strong association with EBV in immunocompromised patients
- Antineutrophil cytoplasmic antibodies (ANCA) and proteinase 3 (PR3) levels are not elevated in association with DLBCL.

Pathology

- Diffuse submucosal discohesive cellular infiltrate composed of medium to large cells with large round to oval vesicular (noncleaved) nuclei and several membrane-bound small nucleoli or a single centrally located prominent eosinophilic nucleolus
- Mitotic activity, necrosis, and apoptotic figures can be seen.
- Immunohistochemistry is essential in confirming the diagnosis and in differentiating a malignant lymphoma from carcinoma:
 - Immunoreactivity present for leukocyte common antigen (CD45) and pan B-cell markers, including CD20, CD79a, CD22, PAX5

Fig. 3-87. Sinonasal diffuse large cell B-cell lymphoma.

A, Diffuse submucosal dyscohesive cellular infiltrate. **B**, The neoplastic cells are composed of medium to large cells with large round to oval vesicular (noncleaved) nuclei and centrally located prominent eosinophilic nucleoli and smaller membrane-bound nucleoli; increased mitotic activity is present. **C**, This cellular infiltrate is immunoreactive for (*left panel*) leukocyte common antigen and the (*right panel*) B-cell marker CD20. **D**, p63 immunoreactivity may be present. Unless a diagnosis of lymphoma is considered to include evaluation for hematolymphoid markers, the presence of p63 may result in a misdiagnosis of an epithelial malignancy.

- Positive for surface or cytoplasmic immunoglobulin:
 - IgM > IgG > IgA
- Melanoma-associated antigen (MUM1) expression (nuclear staining):
 - MUM1 gene encodes a transcription factor responsible for development of B, T, plasma, dendritic, and myeloid cells.
 - MUM1 expression originally recognized by upregulation in multiple myeloma, however not specific for plasmacytic differentiation and can be seen in a variety of neoplasms, including:
 - DLBCL
 - Follicular lymphoma
 - Burkitt lymphoma
 - Hodgkin's lymphoma
 - Anaplastic large cell lymphoma
 - Lymphoplasmacytic lymphoma
 - Chronic lymphocytic leukemia
 - Marginal zone lymphoma
 - Primary mediastinal large B-cell lymphoma
 - Primary effusion lymphoma
 - Melanoma
- BCL6 in approximately 60%
- CD10 expression occurs in 40%.
- CD5 and CD30 in approximately 10%
- Cyclin D1 (BCL1) negative
- High proliferation index by Ki67 of > 20% and often > 80%
- p53 positive in approximately 40%
- p63 may be positive (usually focal/scattered positive cells):
 - In the setting of a sinonasal small round cell malignancy in biopsy material, the presence of

p63 may suggest an epithelial or myoepithelial lesion, especially if a diagnosis of a lymphoma is not considered.

- Absence of other epithelial markers and presence of immunostaining for hematolymphoid markers (LCA and B-cell markers) results in a diagnosis and prevents misdiagnosis.
- Hans algorithm subclassifies DLBCL into germinal center B-cell type (GCB) versus nongerminal center B-cell type (non-GCB):
 - GCB: CD10+, BCL6+, MUM1-
 - Non-GCB: CD10-, BCL6+, MUM1+
 - GCB DLBCL may have better prognosis than non-GCB DLBCL.
- Cytogenetics and molecular genetics:
 - Clonal rearranged immunoglobulin heavy- and light-chain genes
 - *BCL2* and *BCL6* rearranged in approximately 20% and 30%, respectively
 - *BCL6* mutation in approximately 70%
 - Mutations of *TP53* in approximately 22%
 - *MYC* rearranged in less than 10%:
 - *MYC* rearrangement is a molecular hallmark of Burkitt lymphoma.
 - In DLBCL *MYC* rearrangement more frequent in HIV-infected patients and in extranodal lymphomas
 - Usually EBV negative except in setting of immunodeficiency
 - CGH studies show various chromosomal gains and losses.

Differential Diagnosis

- Carcinoma
- Granulomatosis with polyangiitis (GPA) (formerly Wegener granulomatosis) (see Table 3-10)
- Sinonasal undifferentiated carcinoma
- Nasopharyngeal-type undifferentiated carcinoma
- Mucosal malignant melanoma
- Anaplastic plasmacytoma (Fig. 3-88):
 - Anaplastic variant of extramedullary plasmacytoma is rare.
 - Clinicopathologic features of this uncommon neoplasm are not well established in the literature.
 - Tends to be more common in men than in women; occurs over a wide age range from 37 to 89 years
 - In the upper aerodigestive tract the most common site of occurrence is sinonasal tract; less often occurs in the tonsil and nasopharynx.
 - Most common clinical complaints include nasal obstruction, a mass, or epistaxis
 - All lesions are solitary and extramedullary.
 - No association with previous or concurrent multiple myeloma

- Histologically, the tumors are submucosal and composed of immature-appearing cells with round nuclei, prominent nucleoli, vesicular to dispersed nuclear chromatin, and a variable amount of eosinophilic cytoplasm:
 - Nuclear pleomorphism, mitotic activity, and necrosis are consistently present.
- Foci of differentiated plasma cells and Dutcher bodies can be identified.
- Immunohistochemistry:
 - Light chain restriction ($\kappa > \lambda$)
 - Consistent reactivity in the majority of cases for CD138 (Syndecan-1), vimentin, and CD79a
 - Minority of cases show epithelial membrane antigen (EMA), CD30, CD45 reactivity
 - No immunoreactivity for CD20, cytokeratin, S100 protein, melanocytic markers, neuroendocrine markers, and myogenic markers
- Radiation therapy is preferred treatment and may be supplemented by surgical resection and/or chemotherapy.
- Variable prognosis, some patients alive with no evidence of disease or dead of unrelated causes, some patients alive with recurrent disease, and a minority of patients who develop multiple myeloma.

Treatment and Prognosis

- For B-cell lymphomas, including DLCL, the prognosis is dependent on the clinical stage.
- Majority (approximately 75%) of sinonasal DLCL are localized/low clinical stage disease (Ann Arbor IE/IIIE).
- Treatment primarily includes radiotherapy and chemotherapy.
- Surgical resection may be needed for symptomatic relief.
- Five-year survival rates vary in the literature from 29% to 80%.
- Systemic failure includes increased risk of dissemination to nodal and extranodal sites below the diaphragm (e.g., para-aortic lymph nodes, GI tract).

EWING FAMILY OF TUMORS (EFT) (Figs. 3-89 through 3-91)

Definition: Group of high-grade primitive small round cell sarcomas with (variable) neuroectodermal differentiation and defined by the presence of translocation between Ewing sarcoma (*EWS*) gene on chromosome 22 and the *FLI-1* gene on chromosome 11.

- EFT includes Ewing sarcoma (EWS) and primitive (peripheral) neuroectodermal tumor (PNET); recently the designation PNET was dropped as a synonym for EWS to minimize confusion with

Fig. 3-88. Anaplastic plasmacytoma.

A, This neoplastic infiltrate was located within the submucosa of the maxillary sinus and is composed of immature-appearing cells with pleomorphic round nuclei, prominent nucleoli, vesicular to dispersed nuclear chromatin, variable amount of eosinophilic cytoplasm, and scattered mitotic figures; scattered mature plasma cells including the presence of a paranuclear clear zones are seen. **B,** Cells with intranuclear hyaline inclusions (Dutcher bodies) are present (arrowhead). **C,** Immunoreactivity is present for CD138; in addition, kappa light chain restriction, CD79, vimentin, and EMA reactivity was present (not shown).

similarly named lesions in the central nervous system and female genital tract, which consistently lack *EWSR1* gene rearrangement.

Synonyms: Peripheral neuroectodermal tumor; peripheral neuroepithelioma; peripheral neuroblastoma; adult neuroblastoma; peripheral primitive neuroectodermal tumor

Note: Ewing sarcoma is generally considered a malignant primary bone tumor but may occur outside bone, including in soft tissues referred to as extraosseous (or extraskeletal) Ewing sarcoma.

- EWS and PNET share the common cytogenetic abnormality $t(11;22)(q24;q12)$, supporting the notion that these two tumors are histogenetically related:

- Previously differentiation of EWS from PNET was based on the presence (PNET) or absence (EWS) of neural differentiation.
- Now considered to represent a single type of tumor grouped as members of the EWS/PNET family instead of separate although related tumor types with attempted differentiation predicated on presence or absence of neural differentiation
- Undifferentiated (Ewing-like) sarcoma: the designation undifferentiated/unclassified sarcoma recently introduced for a subset of sarcomas that cannot be classified into any presently defined categories lacking any apparent definable line of

Fig. 3-89. EWS/PNET of the sinonasal tract.

A, Markedly cellular tumor with (*left panel*) sheetlike and (*right panel*) lobular growth with little stromal component. **B**, Densely cellular infiltrate composed of uniform small round cells with round to oval nuclei, fine-appearing (powdery) nuclear chromatin, distinct nuclear membrane, inconspicuous to small nucleoli, scanty pale to vacuolated (clear-appearing) cytoplasm, and indistinct cell borders. **C**, Intracytoplasmic glycogen as seen by the presence of diastase-sensitive, PAS-positive material (*left panel*, PAS; *right panel*, PAS with diastase digestion). **D**, CD99 immunoreactivity.

differentiation by available technologies. These undifferentiated/unclassified sarcomas may have spindle cell, pleomorphic, round cell, and epithelioid cytomorphology. Within the round cell category, there are genetic subsets characterized by *CIC-DUX4* gene fusion resulting in t(4;19) or t(10;19) chromosome translocation. This translocation results in upregulation of a group of genes in the Ewing family of tumors that are similar to genes upregulated in conventional EWS, suggesting a close molecular biologic relationship and the suggested designation of undifferentiated (Ewing-like) sarcoma.

Clinical

- Primarily a tumor of areas other than head and neck sites, including:
 - Thoracopulmonary (Askin tumor) > extremities, abdominal and pelvic regions
- Rare tumor of the head and neck:
 - 2% to 10% occur in the head and neck
 - Most common sites of involvement include the skull and jaws
 - Less common sites of involvement include the sinonasal tract, orbit, and various mucosal sites
- Slightly more common in men than in women
- Predominantly but not exclusively a tumor of children and young adults; occasionally may occur in older adults
- In the sinonasal tract, most commonly occurs in the maxillary sinus and nasal fossa
- Symptoms include pain, a mass lesion, and nasal obstruction:
 - Dural, orbital, or brain involvement may occur.
- Laboratory findings:
 - No specific findings
 - In contrast to neuroblastoma, catecholamine levels are not elevated.

Fig. 3-90. EWS/PNET of the sinonasal tract.

A, Densely cellular composed diffuse (sheetlike) growth with little stromal component. **B**, Neoplastic cells lack cohesiveness and are small and round with irregular-appearing round to oval nuclei with coarse (clumped) nuclear chromatin, variably prominent nucleoli, and scant cytoplasm. **C**, Increased mitotic activity is present. **D**, Necrosis may be present. **E**, Pseudorosettes (Homer Wright) can be identified. **F**, Intracytoplasmic glycogen as seen by the presence of diastase-sensitive, PAS-positive material (*left panel*, PAS; *right panel*, PAS with diastase digestion). Immunoreactivity is present for **G**, CD99 (membranous staining);

Continued

Fig. 3-90, cont'd

H, Fli-1 (nuclear); **I**, neuron specific enolase (nuclear and cytoplasmic); **J**, Synaptophysin (cytoplasmic).

- Radiology:
 - Bony erosion may or may not be present.
- Site for the Ewing sarcoma gene is 22q12.
- Heritable retinoblastoma may predispose to ES and perhaps to a subset of poorly differentiated neuroectodermal tumors in the sinonasal region that may be related to olfactory neuroblastoma.

Pathology

Gross

- In the sinonasal tract, these tumors can be polypoid.
- Multilobular, grey-white, and glistening with associated hemorrhage; ulceration is often present.

Histology

- Markedly cellular with a diffuse (sheetlike) or lobular growth with little stromal component; when present the stromal component includes thin fibrous strands separating tumor lobules:

- Trabecular or cordlike growth may occasionally be present.
- Composed of uniform small round cells with round to oval nuclei, fine-appearing (powdery) nuclear chromatin, distinct nuclear membrane, inconspicuous to small nucleoli, scanty pale to vacuolated (clear-appearing) cytoplasm, and indistinct cell borders
 - Vacuolated (clear-appearing) cytoplasm is due to glycogen deposition, which may result in nuclear indentation.
 - Occasionally spindle cell foci may be present.
- Mitotic activity is variable but can be high, ranging from 5 to 10 mitoses per 10 high-power fields.
- Prominent intratumoral vascularity but the presence of thin-walled vessels may be compressed and obscured by the densely cellular proliferation.
- Degenerative changes and/or necrosis may result in a pseudoalveolar pattern, suggesting a possible diagnosis of rhabdomyosarcoma.

Fig. 3-91. EWS/PNET break-apart fluorescent in situ hybridization (FISH).

Normal *EWSR1* gene is represented by the overlapping red and green signals; separate red and green signals represent the split of the *EWSR1* gene as a result of the translocation. (From Dabbs: *Diagnostic immunohistochemistry*, ed 4, Philadelphia, 2014, Saunders, Fig. 8-2, C.)

- Pseudorosettes (Homer Wright) present in most cases, and less often true neural rosettes (Flexner-Wintersteiner) can be found.
- Histologic variants of EFT include:
 - Atypical variant, also referred to as large cell variant, characterized by larger nuclei with atypical features as compared with “conventional” EWS/PNET
 - Clear cell variant
 - Hemangioendothelioma-like
 - Adamantinoma-like:
 - Rare variant representing approximately 5% of cases
 - Nested, epithelioid growth pattern with stromal desmoplasia
 - Tumor nests show peripheral nuclear palisading and contain large polygonal cells with irregular contours, hyperchromatic nuclei, prominent nucleoli, and moderate amount of cytoplasm.
 - Squamous pearls may be seen.
 - Cells show strong pancytokeratin and focal high molecular weight cytokeratin staining.
 - Sclerosing variant
- Histochemistry:
 - Abundant glycogen as seen by the presence of diastase-sensitive, PAS-positive, intracytoplasmic material
- Immunohistochemistry:
 - CD99 (MIC2) reactivity (membranous) seen in nearly all cases:
 - Gene product of MIC2 is a membranous glycoprotein detected by a number of antibodies (MIC2; O13; HBA-71, p30/32, and 12E7).
 - Represents the monoclonal antibody to the *EWS/FLI1* fusion product
 - CD99 is highly sensitive but lacks specificity, as a wide variety of tumor types express CD99, including (but not necessarily limited to) T-lymphoblastic lymphoma, synovial sarcoma (poorly differentiated), small cell osteosarcoma, rhabdomyosarcoma, desmoplastic small round cell tumor, small cell undifferentiated neuroendocrine carcinoma, Merkel cell carcinoma, mesenchymal chondrosarcoma, neuroblastoma.
 - CD99 must be used in conjunction with a broad panel of antibodies in the diagnosis and differential diagnosis of EWS/PNET.
 - Friend leukemia integration-1 (FLI-1) reactivity (nuclear) seen in a large percentage of cases; staining for vascular endothelial markers including CD31, ERG, others is negative.
 - Vimentin positive
 - Cytokeratin (AE1/AE3, CAM5.2) staining may focally be present in up to a third of cases:
 - Staining is typically focal and dot-like but may be strong and diffuse:
 - Adamantinoma variant typically has strong cytokeratin (AE1/AE3) staining and may show reactivity with high molecular weight cytokeratins
 - Typically, do not express high molecular weight cytokeratins
 - c-kit (CD117) may be present in approximately 25% of cases.
 - Reactivity for at least one neural marker, including NSE, S100 protein, synaptophysin chromogranin, CD56, neurofilament protein (NFP), or GFAP, may be present.
 - Absence of desmin, myoglobin, myogenin (myf-4), leukocyte common antigen, and calretinin reactivity
- Electron microscopy:
 - Presence of dense core (neurosecretory) granules, neurotubules, or neuritic processes
 - Neuritic processes contain intermediate filaments, microtubules
 - Poorly defined desmosomes and tight junctions
- Cytogenetics and molecular genetics:
 - Majority of cases (90% to 95%) show consistent reciprocal translocation between chromosome 11 and chromosome 22:
 - Most common translocation involves *EWSR1* gene (chromosome 22) and *FLI-1* gene (chromosome 11).

BOX 3-2 Tumors with EWSR1 Gene Rearrangements**Soft Tissue Tumors**

- Ewing family of tumors
- Desmoplastic small round cell tumor
- Myxoid liposarcoma
- Extraskeletal myxoid chondrosarcoma
- Angiomatoid fibrous histiocytoma
- Clear cell sarcoma of soft tissue
- Clear cell sarcoma-like tumors of the gastrointestinal tract
- Primary pulmonary myxoid sarcoma
- Extrasalivary myoepithelial tumors
- Sporadic examples of low-grade fibromyxoid sarcoma, sclerosing epithelioid fibrosarcoma
- Mesothelioma

Non-Soft Tissue Tumors

- Hyalinizing clear cell carcinoma of the salivary gland

- Variant translocations may occur, all involving *EWSR1* gene on chromosome 22.
- A number of tumors other than EFT have *EWSR1* gene rearrangement (Box 3-2).
- *EWS/FLI-1* fusion transcript detected by a variety of molecular techniques, including (but not limited to) fluorescent in situ hybridization (FISH) and reverse transcription-polymerase chain reaction (RT-PCR):
 - FISH and RT-PCR can be performed on formalin-fixed paraffin-embedded tissue.
 - Break-apart probe for *EWSR1* commercially available

Differential Diagnosis

- Olfactory neuroblastoma
- Rhabdomyosarcoma
- Melanotic neuroectodermal tumor of infancy
- Hematolymphoid malignancies
- Small cell neuroendocrine carcinoma
- Mucosal malignant melanoma
- Sinonasal undifferentiated carcinoma
- NUT midline carcinoma
- Mesenchymal chondrosarcoma
- Synovial sarcoma, poorly differentiated
- Small cell osteosarcoma
- Desmoplastic small round cell tumor

NOTE: Although differences can be identified by light microscopic evaluation, often the differentiation of many of these tumor types rests on the immunohistochemical staining profile for a given tumor (see Table 3-6).

Treatment and Prognosis

- Combined multimodality therapy including (multia-gent) chemotherapy, radiation, and surgery (for local disease control) is the preferred treatment.

- Five-year survival rate of sinonasal ES/PNET of 50% to 75%:
 - Represents better overall prognosis as compared with ES/PNET of other sites
- Five-year survival rate for patients with advanced disease of less than 25%
- Local recurrence and distant metastases may occur within 2 years even in patients with localized disease.
- When metastases occur, most common sites include the lungs and bone; lymph node metastasis is less common, occurring in approximately 20% of cases.
- Prognosis has been found to be linked to:
 - Tumor stage:
 - Staging follows that of the Intergroup Rhabdomyosarcoma Study (IRS)
 - Marked improvement in the prognosis with nonmetastatic disease
 - Outcome for patients with recurrent or metastatic disease remains poor.
 - Tumor size:
 - >8 cm associated with adverse behavior
 - p53 alteration:
 - Appears to define a small clinical subset of patients with ES/PNET with a markedly poor outcome
 - Some studies have shown that the presence of type I *EWS/FLI-1* fusion is thought to have a better prognosis than those tumors with other fusion transcripts with:
 - Longer disease-free survival
 - Respond better to chemotherapy
 - Lower proliferation rates
 - Poor histologic/radiologic response at the site of the primary tumor
 - Incomplete radiologic remission of lung metastases after primary chemotherapy
- Targeted therapy:
 - Potential novel targets for therapy are under investigation and may prove beneficial for patients with recurrent or metastatic disease.
- Given the treatment with radiation early in life, there is an increased incidence of radiation-induced sarcoma in these patients in later life.

SINONASAL TRACT SARCOMAS

- In general, sarcomas of the sinonasal tract are uncommon.
- Although uncommon, virtually all types of sarcomas may occur in the sinonasal tract.
- Although also uncommon, among one of the more common sarcomas of the sinonasal tract is rhabdomyosarcoma; see Section 3, Pharynx, and Section 7, Ear and Temporal Bone, for complete discussion.

Fig. 3-92. Sinonasal undifferentiated pleomorphic sarcoma.

The tumor is seen protruding from the left nasal vestibule and invading into the subcutaneous compartment resulting in facial deformity.

Fig. 3-93. Sinonasal undifferentiated pleomorphic sarcoma.

The tumor is characterized by a densely cellular infiltrate with fascicular and storiform growth composed spindle-shaped cells with marked nuclear pleomorphism, hyperchromasia, and increased mitotic activity, including typical and atypical forms; multinucleated giant cells are present.

- Rarely, osteosarcoma, chondrosarcoma, malignant peripheral nerve sheath tumors, liposarcoma, synovial sarcoma, chordoma, and alveolar soft part sarcoma may occur in the sinonasal tract; see Sections 2, Oral Cavity, 3, Pharynx, 4, Neck, and 5, Larynx, for complete discussion of these tumor types.

Undifferentiated Pleomorphic Sarcoma, Not Otherwise Specified (Figs. 3-92 through 3-95)

Definition: High-grade, pleomorphic malignant neoplasm without specific differentiation and not associated with differentiated sarcoma:

- Undifferentiated pleomorphic sarcoma is the current terminology used for sarcomas previously diagnosed collectively as malignant fibrous histiocytoma (MFH).
- MFH was once considered one of the more common soft tissue sarcoma of late adult life primarily affecting the soft tissues of the lower extremity, but with more advanced diagnostic techniques (e.g., immunohistochemistry, molecular analyses) the recognition that MFH was a “wastebasket” diagnosis for lesions more accurately classified into a specific class of sarcomas (e.g., liposarcoma, others) has decreased its incidence and raised question about the validity of its existence.
- Now classified by the WHO under category designated undifferentiated/unclassified sarcoma

Fig. 3-94. Myxofibrosarcoma.

A, Radical resection specimen that included an orbital exenteration showing a mass with gelatinous/mucoid appearance; more solid nongelatinous foci were present.
B, left panel, Histology includes prominent myxoid stroma with associated curvilinear blood vessels and (*right panel*) cells with hyperchromatic nuclei and vacuolated cytoplasm.
C, Cellular areas showing features of the storiform-pleomorphic type were present but represent the minority of the tumor type.

Fig. 3-95. Sinonasal undifferentiated pleomorphic sarcoma, inflammatory fibrosarcoma.

A, Admixture of spindle-shaped and inflammatory cells.
B, At higher magnification malignant cells, including mitotic figure (*right panel*), are seen in association with inflammatory cells.

Clinical

- Uncommon neoplasm in the head and neck:
 - Approximately 3% occur in the head and neck, with the sinonasal tract representing the most common site of occurrence (approximately 31% of cases)
 - The neck is the second most common site of occurrence (approximately 13% of cases).
 - Rare in all other sites of the head and neck, including oral cavity and larynx
- More common in men than in women; occurs over a wide age range but most commonly seen in adults
- In the sinonasal tract the more common sites of occurrence include: maxillary sinus > ethmoid sinus and nasal cavity; rare occurrence in the frontal and sphenoid sinuses
- Symptoms vary and include a mass with or without associated pain, nasal obstruction, epistaxis, facial asymmetry, and proptosis.

- Radiology:
 - Sinus opacification
 - Soft tissue mass with or without osseous destruction/invasion
 - May be entirely intraosseous and in this setting is osteolytic with expansion and erosion of the cortex
- Majority occur de novo; however, evidence supports that some of these tumors are radiation-induced:
 - In association with prior radiation, the latency period is usually a decade or longer from the time of irradiation to the development of the malignancy.

Pathology

Gross

- Nodular- or multinodular-appearing tan-white to gray lesion of varying size; necrosis and hemorrhage may be apparent.
- Myxoid variant appears translucent or gelatinous.

Histology

- Storiform-pleomorphic features are most common:
 - Fascicular and storiform growth patterns:
 - Storiform growth is characterized by neoplastic cells forming short fascicles in a “pinwheel” or “cartwheel” configuration.
 - Hypercellular neoplasm consisting of spindle-shaped to epithelioid-appearing cells marked by nuclear pleomorphism and increased mitotic activity, including typical and atypical forms
 - Multinucleated giant cells, bizarre giant cells with multiple hyperchromatic nuclei are identified
 - Necrosis is commonly seen.
 - Heterologous (metaplastic) bone and cartilage may be present.
- Variable amount of chronic inflammatory cell infiltrate that may include mature lymphocytes, plasma cells, xanthoma (foam) cells with variable numbers of neutrophils and eosinophils; granulomas may be identified.
- Stromal findings include variable fibrosis, hyalinization, myxoid change, and vascularity.
- Histochemistry:
 - Special stains are of little assistance in the diagnosis.
- Immunohistochemistry:
 - Vimentin positive
 - Smooth muscle actin may be focally positive.
 - Giant cells may show CD68 reactivity.
 - Usually there is an absence expression for epithelial markers (e.g., cytokeratins), melanocytic markers (e.g., S100 protein, HMB45, melan-A, tyrosinase), myogenic markers (desmin, myoglobin, myf-4), hematolymphoid markers (LCA, B- and T-cell).

Histologic Variants

- Myxoid variant (myxofibrosarcoma) (see Fig. 3-93):
 - Previously referred to as myxoid malignant fibrous histiocytoma:
 - Defined as tumor with myxoid stroma in at least 50% of the tumor, but prior to considering this diagnosis a myxoid variant of another defined sarcoma type must be excluded.
 - Tend to be multinodular, characterized by cells with low nuclear grade morphology and low mitotic rate
 - Cells are spindle- or stellate-shaped with hyperchromatic nuclei, limited pleomorphism, slightly eosinophilic cytoplasm, and indistinct cell borders.
 - Cellular foci showing features of the storiform-pleomorphic type may be seen but usually are haphazardly arrayed.
 - Myxoid foci may be hypocellular.
 - A variant with predominantly epithelioid morphology described
 - Cells may show features suggestive of lipoblasts, including vacuolated cytoplasm with indentation of the nuclei.
 - Stromal vasculature may include delicate vessels arranged in a curvilinear fashion; tumor cells tend to align along the vessel periphery.
 - Myxoid stroma is rich in acid mucopolysaccharides that are sensitive to hyaluronidase digestion.
 - Overall prognosis thought to be better than that of storiform-pleomorphic type
- Inflammatory variant (see Fig. 3-94):
 - Admixture of histiocytic-appearing cells, xanthomatous cells, and inflammatory cells
 - The inflammatory cells include neutrophils, which:
 - Typically are not associated with necrosis
 - May be intense and obscure the neoplastic cell infiltrate
 - Patients may have constitutional symptoms including fever and peripheral granulocytosis.
- Giant cell variant:
 - Nodular or multinodular growth but may also demonstrate a diffuse growth without nodularity
 - Characterized by the presence of multinucleated giant cells containing numerous (up to 100) round to oval nuclei with vesicular chromatin, identifiable nucleoli, and eosinophilic cytoplasm:
 - Multinucleated giant cells are admixed with mononuclear cells and spindle-shaped cells.

- Diagnosis of giant cell variant requires that the multinucleated giant cells and mononuclear cells represent more than 50% of the tumor.
- Angiomatoid variant (angiomatoid fibrous histiocytoma):
 - Previously referred to as angiomatoid MFH
 - Soft tissue neoplasm of low malignant potential, typically occurring in the superficial soft tissues of the extremities in children and young adults
 - Tendency to locally recur and rarely may metastasize
 - Histology characterized by:
 - Irregular solid masses of histiocytic-like cells:
 - Histiocytic-like cells are usually uniform with round to oval nuclei and slightly eosinophilic cytoplasm.
 - Nuclear atypia and/or hyperchromatic giant cells may be seen.
 - May contain hemosiderin
 - Cystic areas of hemorrhage:
 - Not lined by endothelial cells
 - Outer shell of chronic inflammatory cells, including abundant lymphocytes and plasma cells
 - Uncommonly a prominent myxoid stroma may be present.
 - Unusual features that may be focally seen include clear cells, rhabdomyoblast-like cells, pulmonary edema-like pattern, and tumor cell cords lying in a myxoid stroma.
 - Immunohistochemistry:
 - Reactivity for the epithelial membrane antigen, desmin, smooth muscle actin, muscle specific actin, CD68, and CD99
 - Cytogenetics and molecular genetics:
 - t(12;22)(q13;q12) and t(2;22)(q33;q12) identified
 - *EWSR1-CREB1* and *EWSR1-ATF1* gene fusions identified but also present in:
 - Conventional clear cell sarcoma (of tendons and aponeuroses), clear cell sarcoma-like tumor of the gastrointestinal tract, soft tissue myoepithelial carcinoma, hyalinizing clear cell carcinoma of the salivary gland, primary pulmonary myxoid sarcoma

Differential Diagnosis

- Nodular fasciitis
- Inflammatory myofibroblastic tumor
- Dermatofibrosarcoma protuberans
- Fibrosarcoma
- Spindle cell squamous carcinoma
- Malignant melanoma
- Rhabdomyosarcoma
- Liposarcoma
- Leiomyosarcoma

- Synovial sarcoma, monophasic type
- Malignant peripheral nerve sheath tumor
- Hematolymphoid malignancies

Treatment and Prognosis

- Complete surgical excision is the preferred treatment.
- Radiotherapy may be used for those tumors with positive surgical margins or close surgical margins.
- Chemotherapy is employed in the presence of metastatic disease.
- Lymph node metastasis occurs in less than 15% of cases and unless clinically suspect, neck dissection is of limited value.
- For high-grade lesions:
 - A high recurrence and metastatic rates:
 - Metastases occur to the lung > lymph nodes > liver and bone.
 - Death from disease is common:
 - Reported in more than 75% of patients
 - Median time of 13.5 months
- Prognosis depends on:
 - Depth of tumor:
 - Deep soft tissue tumors more likely to metastasize as compared with tumors of the subcutis
 - Size of tumor:
 - Smaller tumors (less than 2.5 cm) less likely to metastasize as compared with larger tumors
 - Inflammatory cell component:
 - Tumors with increased numbers of acute and chronic inflammatory cells are less likely to metastasize as compared with tumors lacking a significant inflammatory cell infiltrate.

Fibrosarcoma (Figs. 3-96 through 3-98)

Definition: Malignant tumor of fibroblasts and myofibroblasts lacking evidence of other types of cellular differentiation.

Clinical

- Found predominantly in the soft tissues of the lower extremities (thigh and knee area)
- Up to 10% may occur in the head and neck region.
- No gender predilection; may affect all age groups, with the majority of cases occurring in the fourth through sixth decades of life:
 - Not limited to adults and may occur in children
- Common head and neck sites include the nasal cavity and paranasal sinuses; less often may occur in other head and neck sites, including the larynx and neck.

Fig. 3-96. Sinonasal fibrosarcoma, high grade.

A, The tumor is characterized by a fasciculated growth pattern with long sweeping fascicles and a dense spindle-shaped cellular infiltrate; **B**, The cells are pleomorphic with elongated to spindle-shaped hyperchromatic nuclei, scanty cytoplasm, indistinct cell borders, and multiple mitotic figures.

Fig. 3-97. Low-grade fibromyxoid sarcoma.

A, Variably cellular neoplastic proliferation with low to moderate cellularity and a variably myxoid to fibrous-appearing stroma. **B**, Deceptively bland-appearing spindle-shaped cells with small hyperchromatic nuclei and indistinct eosinophilic cytoplasm. **C**, Network of curvilinear and branching capillary-sized blood vessels. **D**, MUC4 immunoreactivity considered sensitive and specific for LGFMS. Additional stains that may be present include vimentin, smooth muscle actin, and muscle specific actin (not shown).

Fig. 3-98. Sclerosing epithelioid fibrosarcoma.

A, Epithelioid cells arranged in nests, cords, and strands embedded in a dense collagenous stroma. **B**, At higher magnification the bland-appearing epithelioid cells have round to oval nuclei, stippled to vesicular chromatin, and scanty clear to eosinophilic cytoplasm. **C**, Hybrid tumor showing foci of sclerosing epithelioid fibrosarcoma (*left*) and low-grade fibromyxoid sarcoma (*right*). **D**, MUC4 staining seen in a majority of cases. The presence of morphologic and molecular overlap between sclerosing epithelioid fibrosarcoma and low-grade fibromyxoid sarcoma suggests a relationship between these tumor types.

- Symptoms vary according to site and include nasal obstruction, epistaxis, pain, dysphagia, or as a solitary mass with or without associated pain.
- Radiology:
 - Soft tissue mass
 - Bone destruction is commonly identified.
- Generally arise de novo but may be linked with prior radiation treatment or in association with old burn scars:
 - In association with prior radiation the latency period is usually a decade or longer from the time of irradiation to the development of the malignancy.

Pathology

Gross

- Unencapsulated, polypoid, or sessile tan-white, firm tumor usually measuring less than 10 cm in diameter
- Sinonasal fibrosarcomas are often associated with bone erosion and/or destruction.

Histology

- Fasciculated growth pattern composed of spindle-shaped cells with scanty cytoplasm and indistinct cell borders

- May be histologically classified as low-grade or high-grade based on tumor cellularity, cellular maturity, and the amount of collagen production:
 - Histologic grading schema has been proposed based tumor differentiation:
 - Low grade = well differentiated
 - High grade = poorly differentiated

Low-grade Fibrosarcoma

- Cellular neoplasm with uniform spindle cells, absence of nuclear hyperchromasia, scattered mitoses, and variable amount of collagen
- Fasciculated growth pattern is distinct.
- Invasive growth is present.

High-grade Fibrosarcoma

- Hypercellular neoplasm with pleomorphism, hyperchromatic, rounded to oval nuclei, increased mitotic activity, necrosis, and less collagen production
- Loss or indistinct fasciculated growth
- Both low- and high-grade neoplasms lack the marked pleomorphism or multinucleated giant cells more typically seen in undifferentiated pleomorphic sarcoma.
- Heterologous metaplastic elements (bone and cartilage) may be seen particularly in the low-grade type.
- Myxoid stromal changes may be focally seen and may be prominent (see below under “variants”).
- Invasive growth is present including osseous invasion.
- Histochemistry:
 - Special stains of limited assistance in the diagnosis
- Immunohistochemistry:
 - Vimentin positive
 - Actin may be focally positive.
 - Usually absent expression for epithelial markers (e.g., cytokeratins), melanocytic markers (e.g., S100 protein, HMB45, melan A, tyrosinase), myogenic markers (desmin, myoglobin, myf-4), hematolymphoid markers (LCA, B- and T-cell), vascular endothelial markers (CD31, CD34)
- Fibrosarcoma variants include:
 - Low-grade fibromyxoid sarcoma (LGFMS; see Fig. 3-96):
 - Also referred to as Evans tumor
 - Generally a tumor of deep soft tissues
 - Tumors are characterized by deceptively bland-looking morphology with low to moderate cellularity composed of relatively bland spindle-shaped cells with small hyperchromatic nuclei and indistinct eosinophilic cytoplasm
 - Mild nuclear pleomorphism and low mitotic rate
 - Variably fibrous and myxoid stroma is present with tendency of these tumors to be more

fibrous; transition between fibrous and myxoid areas may be seen.

- Network of curvilinear and branching capillary-sized blood vessels seen in myxoid areas
- Overall deceptively bland histomorphologic appearance with difficulty in determining malignancy in primary tumor; tendency for recurrence and/or metastasis:
 - Recurrence(s) and metastasis may show similar bland histomorphology as the primary tumor or may show increased cellularity and mitotic activity
- Immunoreactivity:
 - MUC4 immunoreactivity (cytoplasmic) considered sensitive and specific for LGFMS
 - Vimentin, smooth muscle actin, muscle specific actin may be present.
 - p63 staining may be present (weak focal).
- Cytogenetic and molecular genetics:
 - Characterized by the specific translocation t(7;16)(q33;p11) and corresponding fusion gene *FUS-CREB3L2*
 - Alternative *EWSR1-CREB3L1* gene fusion identified:
 - Expands spectrum of gene fusions that characterize LGFMS
 - Suggest *EWSR1* gene may substitute for the function of *FUS* in gene fusions of sarcoma
- Sclerosing epithelioid fibrosarcoma (SEF, see Fig. 3-97):
 - Unusual aggressive fibroblastic neoplasm composed of cords of bland epithelioid cells embedded in a dense collagenous stroma
 - Cells arranged in nests, cords, strands, and occasional acini and alveoli
 - Cells have round to oval nuclei, stippled to vesicular chromatin, and scanty clear to eosinophilic cytoplasm
 - Some SEF cases show morphologic and molecular overlap with low-grade fibromyxoid sarcoma (hybrid tumors), suggesting a relationship between these tumor types.
 - Immunohistochemistry:
 - MUC4 staining (cytoplasmic) seen in a majority of cases
 - *FUS* rearrangement
 - Vimentin positive
 - Epithelial membrane antigen (up to 50% of cases) with membranous staining
 - S100 protein and NSE may be focally positive.
 - No reactivity for desmin, smooth muscle actin, HMB-45, CD68 (KP-1), and leukocyte common antigen

- Cytogenetic and molecular genetics:
 - Characterized by the translocation t(11;16) (p13;p11) and corresponding fusion gene *FUS-CREB3L1*:
 - MUC4-positive SEFs with FUS rearrangement are likely closely related to low-grade fibromyxoid sarcoma.
 - MUC4-positive SEFs that lack FUS rearrangement may be related to low-grade fibromyxoid sarcoma but could have alternate fusion partners, including EWSR1.
 - SEF without MUC4 expression may represent a distinct group of tumors.

Differential Diagnosis (for Fibrosarcoma)

- Nodular fasciitis
- Fibromatosis
- Inflammatory myofibroblastic tumor
- Undifferentiated pleomorphic sarcoma
- Spindle cell squamous carcinoma
- Spindle cell malignant melanoma
- Malignant peripheral nerve sheath tumor
- Synovial sarcoma, monophasic type

Treatment and Prognosis

- Surgical excision to include tumor-free margins is the preferred treatment:
 - Lymph node metastasis is rare; therefore, radical neck dissection is not warranted.
- Adjunctive radiotherapy may be of assistance, but there is no definitive proof as to its efficacy in treating fibrosarcomas.
- Radiotherapy may be used for those tumors with positive surgical margins or close surgical margins and/or for high-grade tumors.
- Prognosis is primarily related to the adequacy of surgical excision.
- Local recurrence likely the result of inadequate resection has been reported to occur in from 50% to 72% of patients:
 - Local recurrence usually occurs within the first 2 postoperative years but may be latent and occur many years following resection.
- Metastatic disease primarily occurs to the lungs and bone.
- Overall 5-year survival rates range from 50% to 70%
- Factors affecting prognosis include:
 - Tumor grade:
 - Low grade associated with high cure rate
 - High grade associated with very low cure rate
 - Tumor size:
 - Worse prognosis associated with tumors greater than 5 cm in greatest dimension

- Adverse prognosis associated with:
 - Positive surgical margins
 - Extension into contiguous anatomic compartments (skin, sinuses)
 - Osseous and neural invasion

Additional Notes

Infantile Fibrosarcoma

- More common in males than in females
- Most common in the upper and lower extremities but up to 15% may occur in the head and neck
- Histologically similar to fibrosarcomas of adults
- Distinctive *ETV6-NTRK3* gene fusion is present.
- Overall have a better prognosis as compared with adult fibrosarcomas with less likelihood of local recurrence or distant metastasis:
 - Applicable to children 5 years or younger
 - Children 10 years and older have a prognosis similar to those of adults.
- Overall 5-year survival of 85% to 95%
- Gains in chromosomes 8, 11, 17, 20 reported in children less than 2 years old

Leiomyosarcoma

(Figs. 3-99 through 3-103)

Definition: Malignant tumor of smooth muscle.

NOTE: Given the relative absence of smooth muscle in the head and neck region, the histogenesis appears to arise from vascular structures.

Fig. 3-99. Sinonasal leiomyosarcoma.

Large, firm polypoid mass with a tan-white appearance.

Fig. 3-100. Sinonasal leiomyosarcoma, low grade.

A, Submucosal cellular infiltrate with a fascicular growth. **B**, Cellular neoplasm composed of interlacing bundles intersecting at right angles. **C**, The neoplastic cells are uniform with elongated, centrally located, blunt-ended, cigar-shaped nuclei and indistinct eosinophilic cytoplasm. **D**, Nuclear pleomorphism, hyperchromasia, and a mitotic figure (*upper right*). The overall mitotic count was 4 mitoses per 10 high-power fields that in conjunction with infiltrative growth (not shown) conferred the diagnosis of a low-grade leiomyosarcoma.

Clinical

- Approximately 4% of all leiomyosarcomas arise in the head and neck.
- No gender predilection; occurs in a wide age range but most common in the sixth decade of life
- In the head and neck, the most common sites of occurrence are:
 - Oral cavity (buccal mucosa, gingiva, tongue, floor of mouth) > sinonasal tract > skin and subcutaneous tissue
 - Less common sites of occurrence include larynx, trachea, neck, hypopharynx, orbit, external auditory canal.
- Most common symptoms are dependent on site:
 - Sinonasal tract: nasal obstruction, pain, and epistaxis
 - Oral cavity: painless mass, ulceration
 - Duration of symptoms usually is over extended periods of time.
- Radiology:
 - Soft tissue density
 - Sinus opacification
 - Bone erosion and/or invasion
- Majority occur de novo, but some sinonasal tract tumors reported to occur following irradiation or cyclophosphamide exposure
- Greater frequency of occurrence of leiomyosarcomas (in general, not necessarily those of the head and neck) in the immunocompromised patient, including:
 - Post-transplantation (e.g., renal, cardiac, liver)
 - AIDS
 - Tendency to occur in children
 - Tendency to occur in relationship to viscera (e.g., gastrointestinal tract, lung, other)

Fig. 3-101. Sinonasal leiomyosarcoma, high grade.

A, Submucosal cellular infiltrate with a fascicular growth; the degree of cellularity in this tumor even at low magnification is greater than that seen in the previous illustration. **B**, Cellular neoplasm composed of interlacing bundles intersecting at right angles with markedly pleomorphic nuclei. **C** and **D**, The neoplastic cells are pleomorphic, hyperchromatic with prominent nucleoli and increased mitotic activity. The overall mitotic count was 10 mitoses per 10 high-power fields that in conjunction with infiltrative growth (not shown) conferred the diagnosis of a high-grade leiomyosarcoma.

Fig. 3-102. Leiomyosarcoma histologic variants.

Histologic variants of leiomyosarcoma include **(A)** epithelioid and **(B)** inflammatory.

Fig. 3-103. Special stains in leiomyosarcoma.

Special stains that may assist in the diagnosis of leiomyosarcoma include (A) Masson trichrome showing deep red, longitudinal lines consistent with cytoplasmic myofibrils; (B) smooth muscle actin; (C) desmin.

- May be multifocal
- May disseminate and be lethal
- EBV found in these tumors by immunohistochemistry, in situ hybridization, and/or PCR:
 - Referred to as EBV-associated smooth muscle tumors

Pathology

Gross

- Circumscribed but not encapsulated, tan-white to pink-red, rubbery to firm, polypoid or sessile lesion usually measuring >5 cm in diameter
- Ulceration, hemorrhage, necrosis, and invasion of adjacent structures are often identifiable.

Histology

- Cellular neoplasm composed of interlacing bundles of spindle-shaped cells; typically the interlacing bundles intersect at right angles:
 - Fascicular growth similar to that seen in fibrosarcoma may be present.
- Neoplastic cells are elongated with centrally located, blunt-ended, cigar-shaped nuclei and eosinophilic cytoplasm:
 - Perinuclear vacuole or clear halo may be seen, giving the nucleus an indented or concave contour.
- Variable degree of cellular anaplasia with nuclear pleomorphism, nuclear hyperchromasia, and increased mitotic activity (typical and atypical forms) can be seen.
- Infiltrative growth can be seen and is indicative of malignancy.
- Multinucleated giant cells are common.
- Nuclear palisading may be prominent, which may suggest a diagnosis of a peripheral nerve sheath tumor.
- Stroma tends to be richly vascular with close apposition of the tumor with the vascular structures.
- Given the relative dearth of smooth muscle in the sinonasal tract (and oral cavity), the presumed origin

for many leiomyosarcomas of these sites (as well as other mucosal sites of the upper aerodigestive tract) is from vascular smooth muscle:

- Tumors can be seen originating from or in close association with blood vessels (arteries and veins, arterioles and venules).
- Other than relationship to vascular walls, the histology is similar to nonvascular-derived leiomyosarcoma.
- Epithelioid cells and myxomatous change may be seen and occasionally may predominate, giving rise to so-called epithelioid leiomyosarcoma and myxoid leiomyosarcoma, respectively:
 - Myxoid leiomyosarcoma:
 - Extensive myxoid change may create a gelatinous appearance.
 - A prominent myxoid stroma that is rich in hyaluronic acid is present in between the spindle neoplastic cells.
 - Overall, appears relatively hypocellular, and in the presence of low mitotic rate the overall histology may not be suggestive of a malignant neoplasm.
 - Even mitotic rates of two or less mitotic figures should prompt consideration for a malignancy.
 - Inflammatory leiomyosarcoma:
 - Characterized by the presence of a leiomyosarcoma with prominent inflammatory cell infiltrate including xanthoma cells, lymphocytes, and occasionally neutrophils
 - Not associated with systemic (constitutional) symptoms
 - Other cell types may include:
 - Epithelioid (epithelioid LMS), granular eosinophilic cytoplasm (granular cell LMS), multinucleated osteoclast-like giant cells are unusual findings and may be seen in only a part of a tumor when identified.
- Histochemistry:
 - Cytoplasmic myofibrils can be seen in better differentiated tumors as deep red, longitudinal lines by Masson trichrome stain and purple by phosphotungstic acid-hematoxylin (PTAH) stain.
 - Glycogen is demonstrable as diastase-sensitive, PAS-positive material.
- Immunohistochemistry:
 - Actins (smooth muscle and muscle-specific) positive
 - Desmin reactivity (70% to 80%) present
 - Caldesmon positive (60% to 65%)
 - Usually no immunoreactivity for epithelial markers (e.g., cytokeratins), melanocytic markers (e.g., S100 protein, HMB45, melan A, tyrosinase), myogenic markers (myoglobin, myf-4), vascular endothelial markers (CD31, CD34):

- Cytokeratin expression may occur:
 - usually in a perinuclear localization
 - usually seen in association with desmin reactivity
- S100 protein may be positive.

- Electron microscopy:

- Deeply indented nuclei, numerous well-oriented myofilaments (6 to 8 nm), pinocytotic vesicles, intercellular connections, and a basal lamina enveloping the entire cell membrane

Criteria for Malignancy in Smooth Muscle Tumors

- Criteria for malignancy in distinguishing benign from malignant smooth muscle tumors are not always straightforward and can present challenges in determining benignancy from malignancy:
 - Not true relative to high-grade tumors
- Most important pathologic diagnostic parameter is mitotic activity; to a lesser degree tumor size affects the diagnosis, and the location of the tumor affects the diagnosis.
 - Criteria for malignancy relative to uterine smooth muscle tumors are unique and are not applicable to soft tissue (and head and neck sites).
 - Relative to soft tissue and head and neck:
 - Tumors with one to four mitoses per 10 high-power fields are considered as potentially malignant, especially in conjunction with large tumor size, nuclear atypia, and necrosis.
 - Five or more mitoses per 10 high-power fields is malignant.
 - If tumors have no mitoses or very few mitoses and an absence of nuclear atypia, then the tumor is likely benign, especially if there is significant hyalinization or calcification.

Differential Diagnosis

- Leiomyoma
- Spindle cell squamous carcinoma
- Malignant peripheral nerve sheath tumors
- Fibrosarcoma
- Rhabdomyosarcoma

Treatment and Prognosis

- Radical surgical excision is the preferred treatment.
- Radiation and chemotherapy are of questionable utility.
- Prognosis depends on the site and extent of tumor and is not necessarily contingent on the histology:
 - Tumors limited to the nasal cavity are associated with a good prognosis and are cured following complete removal.
 - Tumor involving both the nasal cavity and paranasal sinuses results in an aggressive neoplasm associated with increased recurrence (70% of

- patients), morbidity, and mortality rates (45% of patients with death occurring within 2 years of the diagnosis).
- Local recurrence occurs frequently and is usually associated with extensive uncontrollable local infiltration.
- Metastases (hematogenous) occur infrequently, approximately 17% of patients:
 - Usually involving the lung
 - Lymph node metastases are infrequent early but can occur late in the disease course.
- Cutaneous leiomyosarcoma:
 - May be separated into tumors confined to the dermis and those that involve the subcutis:
 - Dermal-based:
 - Tend to be small (less than 2 cm)
 - Tend to be histologically low grade
 - May recur but do not metastasize; this is true even for histologically higher-grade tumors.
 - Favorable prognosis

- Subcutaneous tumors:
 - Up to 40% may metastasize.
 - Metastasis most often occurs to the lungs; nodal metastasis is uncommon.
 - Prognosis comparable to soft tissue leiomyosarcomas
- Wide surgical resection is indicated.

Angiosarcoma (AS)

(Figs. 3-104 through 3-107)

Definition: Malignant tumor of endothelial cell origin.

Synonyms: Hemangiosarcoma; lymphangiosarcoma

Clinical

- In general, angiosarcoma is a rare neoplasm accounting for up to 3% of all sarcomas:
 - In contrast to other sarcomas, angiosarcomas have a predilection for cutaneous and superficial soft tissue sites.

Fig. 3-104. Sinonasal angiosarcoma, low-grade.

A and B, Infiltrative submucosal cellular proliferation characterized by proliferation of ramifying and anastomosing vascular channels. **C and D,** Endothelial cells lining the interconnecting lumens are hyperchromatic with endothelial tufts.

Fig. 3-106. Sinonasal angiosarcoma, epithelioid.

A and **B**, This tumor type, rare in the head and neck, is characterized by the presence of pleomorphic epithelioid-appearing cells with round to oval nuclei and prominent nucleoli lining vascular channels as well as in more solid areas; immunoreactivity can be seen for **C**, Factor VIII-related antigen and **(D)** cytokeratin. The epithelioid appearance coupled with the presence of cytokeratin may result in an erroneous diagnosis of a carcinoma.

Fig. 3-107. Epithelioid hemangioendothelioma.

A, The tumor is arising in close association with a vascular space with vascular expansion and luminal obliteration by the neoplastic proliferation. **B**, Neoplastic cells appear as strands with identification of intracellular lumens seen as vacuoles or clear spaces. Immunoreactivity for CD31 and CD34 was present (not shown).

- Angiosarcoma of head and neck mucosal sites is uncommon.
 - In the head and neck, the most common site of occurrence is in the skin and subcutaneous tissue, particularly the scalp, but may occur as a primary tumor of the mucosa of the upper aerodigestive tract, including the sinonasal tract.
- Cutaneous angiosarcomas:
 - More common in men than in women; most often seen in the seventh and eighth decades of life
- Noncutaneous (head and neck) angiosarcomas:
 - No gender predilection; occur in a younger age population as compared with their cutaneous counterparts with the average age of occurrence in the fifth decade of life
 - Most common in sinonasal tract > oral cavity (gingiva, buccal mucosa, palate, tongue, tonsil) > nasopharynx and larynx > other sites
- Symptoms vary according to the site of occurrence and include a mass lesion, epistaxis, nasal obstruction, and headaches.
- Majority of mucosal-based head and neck angiosarcomas arise de novo.
- Secondary angiosarcomas represent those angiosarcomas that occur as a consequence of:
 - Radiation therapy and/or chronic lymphedema:
 - Most commonly seen in breast cancer patients
- Low-grade angiosarcoma:
 - Might be better considered epithelioid (histiocytoid) hemangioma or epithelioid hemangioendothelioma
 - True low-grade angiosarcoma may exist but should show complex anastomosing vascular channels with infiltrative growth composed of hyperchromatic atypical endothelial cells with intraluminal papillae.
- High-grade angiosarcoma
- An epithelioid subtype (epithelioid angiosarcoma) characterized by round to oval pleomorphic cells may rarely be present in head and neck sites.
- Histochemistry:
 - Reticulin stains delineate the vascular lumina with the endothelial cells identified on the luminal side of the reticulin of framework (this contrasts with the reticulin staining seen in hemangiopericytomas).
- Immunohistochemistry:
 - CD31, CD34, Factor VIII-related antigen, and *Ulex europaeus* positive
 - Fli-1 positive (nuclear):
 - Nuclear transcription factor identified in greater than 95% of vascular tumors
 - Also expressed in Ewing sarcoma family of tumors, melanoma, lymphoblastic leukemia, others.
 - ERG positive (nuclear):
 - ETS family transcription factor identified in greater than 95% of vascular tumors
 - Sensitive endothelial marker of vascular differentiation
 - Claudin-5 positive:
 - Tight junction protein expressed in endothelial cells and in some epithelial cells
 - Newer marker potentially useful for angiosarcoma and Kaposi sarcoma, but its complete expression in nonvascular tumors yet to be defined
 - Vimentin positive and actins may be positive.
 - HHV-8 is negative.
 - In general, no immunoreactivity is seen for epithelial markers or melanocytic markers.
 - Epithelioid angiosarcomas may be immunoreactive for cytokeratins.
- Electron microscopy:
 - Partial envelopment of basal lamina along the antiluminal border, pinocytotic bodies, tight junctions between cells, and occasional identification of rod-shaped microtubulated bodies (Weibel-Palade bodies)
- Cytogenetics and molecular genetics:
 - Upregulation of vascular-specific receptor tyrosine kinases, including TIE1, KDR, TEK, and FLT1

Pathology

Gross

- Unifocal to multifocal, nodular, polypoid or ulcerative, ill-defined lesion with a bluish color sometimes surrounded by an erythematous ring; tumor size varies and can reach large sizes.
- Hemorrhage and necrosis may be seen.

Histology

- Characterized by the presence of:
 - Ramifying, interconnecting, or anastomosing vascular channels, which “dissect” through surrounding structures
 - Channels lined by atypical endothelial cells, which are increased in number and characterized by nuclear pleomorphism, hyperchromasia, and increased mitotic activity
 - Endothelial cells pile up along the lumen, creating papillations.
 - Endothelial cells may appear spindle, epithelioid, or polygonal.
- Depending on the cellularity, pleomorphism, mitotic activity, and extent of necrosis, angiosarcomas are divided in two histologic grades:

- High percentage of secondary AS show distinct 8q24 chromosomal gains due to MYC amplification and in 25% coamplification of FLT4 (encoding VEGFR3) identified:
 - Not found in primary AS
 - Not found in postradiation atypical vascular lesions
- 11p13, 13q14, and 17p13 allelic losses

Differential Diagnosis

- Angiolymphoid hyperplasia with eosinophilia
- Hemangioma and lobular capillary hemangioma
- Nasopharyngeal angiofibroma
- Papillary endothelial hyperplasia; may be present in association with:
 - Sinonasal inflammatory polyps, particularly antrochoanal polyps due to infarction
 - Vocal cord polyps
- Epithelioid hemangioendothelioma (EHE) (see Fig. 3-106):
 - Vascular neoplasm with biologic behavior intermediate between hemangioma and angiosarcoma
 - Rare tumor type in head and neck sites
 - Angiocentric tumor arising from or in close association with a blood vessel (usually a vein)
 - Histologically, composed of short strands or solid nests of rounded to slightly spindle (endothelial) cells
 - Definitive light microscopic evidence of vascular differentiation (e.g., distinct vascular channels) is uncommonly seen; tumor cells form small intracellular lumens seen as vacuoles or clear spaces that may contain erythrocytes
 - Cytologically, cells are usually bland with mild pleomorphism and limited to no mitotic activity.
 - Minority of cases show atypical features including nuclear pleomorphism with cytologic atypia, spindling, increased mitotic activity (more than 1 mitotic figure per 10 high-power fields), and necrosis:
 - Cases with atypical features have a more aggressive course with higher rate of metastases.
 - Some authorities prefer to designate these atypical epithelioid hemangioendotheliomas as malignant epithelioid hemangioendothelioma.
 - Immunoreactivity present for:
 - CD31, CD34, FLI1, and ERG
 - Podoplanin (D2-40) positive with uniform cytoplasmic reactivity
 - Cytokeratins (7, 8, 18) and EMA positive in 25% to 40%
 - Weibel-Palade bodies may be seen by electron microscopy.
 - Cytogenetics and molecular genetics:
 - t(1;3)(p36.3;q25) chromosomal translocation that is characteristic of EHE

- WWTR1-CAMTA1 gene fusion:
 - Apparently represents disease-defining gene alteration
 - Present in virtually all EHEs
 - Absent from all other vascular neoplasms
- Due to the low-grade nature of epithelioid hemangioendothelioma, therapy includes surgical resection in a conservative manner to ensure complete excision (i.e., tumor-free margins) without adjuvant radiation or chemotherapy.
- Prognosis:
 - Soft tissue EHE with increasing mitotic activity (>3 mitoses per 50 high-power fields) and large size (>3.0 cm) associated with decreased survival:
 - Patients with high-risk tumors reported to have 5-year disease-specific survival of 59%.
 - Patients with low-risk tumors less likely to develop metastasis (15%) and more likely to survive for longer periods of time.
 - EHE of the head and neck is:
 - Low-grade malignancy with a tendency for local recurrence and regional lymph node metastasis
 - Complete excision with negative margins is the preferred treatment for localized disease.

- Sinonasal glomangiopericytoma
- Kaposi sarcoma
- Malignant melanoma
- Poorly differentiated carcinoma
- Fibrosarcoma

Treatment and Prognosis

- Complete surgical excision is the preferred treatment, especially with well-delineated and solitary tumors.
- Surgery and radiotherapy may be of benefit in multifocal, ill-defined tumors.
- Prognosis is generally poor, with 10% to 15% 5-year survival rates.
- Recurrences are common and tend to occur within 2 years of surgery and are likely due to the facts that:
 - The extent of the tumor is often difficult to determine.
 - Angiosarcomas often extend beyond their apparent macroscopic limits, which must be accounted for in therapeutic management of these tumors.
- Metastases are uncommon, and when they occur the common metastatic sites include lungs and lymph nodes.
- Prognosis correlates with:
 - Tumor size:
 - Tumors <7 cm in diameter having a better prognosis than tumors measuring >7 cm

- Upper respiratory tract angiosarcomas may have a better prognosis than their cutaneous counterparts and may relate to:
 - Tendency to occur at a younger age
 - Lower incidence of persistence, recurrence, or metastasis
 - Higher salvage rate
 - Greater percentage of patients with no evidence of disease on follow-up
 - Lower morbidity and mortality rates

Low-Grade Sinonasal Sarcoma with Neural and Myogenic Differentiation (LGSSNMF) (Figs. 3-108 and 3-109)

Definition: Recently described distinct spindle cell sarcoma of the sinonasal region characterized by concomitant neural and myogenic differentiation.

NOTE: Whether in fact LGSSNMF truly represents a bona fide independent neoplasm instead of a neoplasm that should be subsumed in another defined tumor category (e.g., neurogenic, fibrohistiocytic, other) remains to be determined, requiring the identification of more cases reported in the literature. For the purposes of this text, LGSSNMF is described as an independent entity with the proviso that classification may or may not change in the future.

Synonym: Biphenotypic sinonasal sarcoma (may eventually represent preferred terminology).

Clinical

- Fewer than 50 cases reported in the literature
- More common in women than men; occur over a wide age range from 24 to 85 years (mean, 52 years):
 - Striking predilection for women in the fifth decade of life (30% of cases)
- Presenting symptoms include difficulty breathing, facial pressure, and congestion:
 - Facial pain and mild epiphora occasionally present
 - Some patients reported to have had a history of sinonasal surgery for apparently benign processes.
- Most tumors involved multiple sites in the sinonasal region:
 - Nasal cavity (54%) and ethmoid sinus (57%) were the most commonly involved areas, either singly or in combination.
 - Tumors may extend to orbit, cribriform plate, or into cranial vault.
- Imaging:
 - Heterogeneously enhancing, destructive lesion
- No known etiologic factors
- No evidence of association with neurofibromatosis

Pathology

Gross

- No distinct gross features:
 - Described as multiple polypoid red/pink to tan or gray fragments measuring up to approximately 4 cm in greatest dimension
 - Tissue fragments described as somewhat more firm than typical inflammatory nasal polyps

Histology

- Poorly circumscribed and unencapsulated cellular spindle cell neoplasm with uniform, elongate nuclei, and an infiltrative growth pattern:
 - Overall, cellularity very high with only a mild degree of variability within a given tumor
 - Tumor cells showed highly uniform, elongate nuclei, focally wavy to buckled in a minority of instances
 - Despite the cellularity, only rare mitotic figures seen; spindle cells were organized into medium-to-long fascicles.
 - Areas of classic “herringbone” pattern identified in most cases
 - Interstitial collagen typically scanty to moderate and arrayed in delicate strands
 - Absence of dense or ropey collagenous matrix
 - Infiltrative growth appreciated at low power, including infiltration of sinonasal bones
 - A striking and characteristic finding in the majority of cases include concomitant, apparently benign epithelial proliferation:
 - Composed of surface-type respiratory epithelium, forming invaginations of small glands or cystic spaces beneath the mucosal surface
 - Glandular structures were intimately admixed with neoplastic spindle cells, imparting a morphologic picture reminiscent of adenocarcinoma of the female genital tract.
 - A prominent hemangiopericytomatous vascular pattern may also be present.
 - Scattered small lymphocytes often sprinkled throughout the neoplastic component
 - Ulceration, hemorrhage, and necrosis not prominent features
 - Focal rhabdomyoblastic differentiation identified in a minority of cases (11%) characterized by:
 - Large cells with bright, eosinophilic cytoplasm, prominent nuclei, and focal cross-striations
- No evidence to suggest origin from a nerve
- Immunohistochemistry:
 - S100 protein positive in all tumors, at least focally:
 - Diffuse (57%), patchy (36%), or restricted to isolated tumor cells (7%)

Fig. 3-108. Low-grade sinonasal sarcoma with neural and myogenic differentiation (LGSSNMF).

A, Polypoid lesion showing a submucosal spindle cell proliferation, characteristically with associated benign epithelial glandular proliferation. **B**, Higher magnification of the combined spindle cell proliferation with fascicular pattern of growth and benign glands. **C**, Cellular spindle cell proliferation showing “herringbone” pattern of growth. **D**, Spindle cells wavy to buckled appearance suggestive of neurogenic differentiation. **E**, In spite of increased cellularity the nuclei are uniform in appearance, lacking significant pleomorphism and increased mitotic activity; a scanty amount of intercellular collagen is present. **F**, Hemangiopericytomatous vascular pattern may also be present (*lower right*).

Fig. 3-109. Low-grade sinonasal sarcoma with neural and myogenic differentiation (LGSSNMF).

Immunoreactivity includes (A) S100 protein and (B) muscle-specific actin. S100 protein is at least focally present in all cases and in a majority of cases is diffuse and strong. Concomitant expression of actins (SMA or MSA) is seen in a majority of cases and often is diffuse.

- Concomitant expression of either actins (SMA or MSA) seen in 96% of the cases:
 - Diffuse (52%), patchy (39%), isolated tumor cells (9%)
- Diffuse MSA positive in 43%
- Additional reactivity may include:
 - CD34 (focal more often than diffuse)
 - Focal desmin
 - Weak EMA
 - Keratin (AE1/AE3) very focal
 - No reactivity for myogenin, estrogen receptor (ER), and progesterone receptor (PR)
- Electron microscopy
 - Moderate amount of intermediate filaments and rough endoplasmic reticulum

- Occasional subplasmalemmal filaments with dense bodies
- Intracellular collagen fibrils readily identified
- No desmosomes, pinocytotic vesicles, basal lamina, or interdigitating processes were seen.
- Cytogenetics and molecular genetics:
 - RT-PCR for SYT-SSX1 and SYT-SSX2 negative in 18 cases evaluated
 - t(2;4)(q37.1;q31.3) chromosomal translocation in two cases:
 - Distinctive cytogenetic signature not being reported in any of the neoplasms considered in the differential diagnosis (see below) supports the notion that LGSSNMF is a separate biological entity likely characterized by a specific fusion gene.
 - Recurrent chromosomal translocation t(2;4)(q35;q31.1) resulting in a PAX3-MAML3 fusion protein reported:
 - Potent transcriptional activator of PAX3 response elements
 - LGSSNMF characterized by aberrant expression of genes involved in neuroectodermal and myogenic differentiation closely simulating developmental roles of PAX3

Differential Diagnosis

- Fibrosarcoma
- Malignant peripheral nerve sheath tumor
- Synovial sarcoma, monophasic
- Malignant triton tumor
- Teratocarcinosarcoma
- Solitary fibrous tumor
- Sinonasal glomangiopericytoma
- Cellular schwannoma
- Schneiderian papilloma
- Respiratory epithelial adenomatoid hamartoma

Treatment and Prognosis

- Surgery is the treatment of choice with/or without radiotherapy and included:
 - Surgical excision
 - Craniofacial resection in three cases for recurrent disease, including orbital exenteration in one case
- Clinical follow-up ranged from less than 1 year to 28 years (mean, 8.3 years):
 - Local recurrences reported in 44% of cases
 - Disease recurred locally from less than 1 year to a maximum of 9 years after treatment
 - Fourteen patients alive and two died from other causes
 - No known regional or distant metastases, and no patients died of disease

Fig. 3-110.

Sinonasal teratocarcinosarcoma characterized by variable admixture of epithelial (squamous nests), small round cell (neuroectodermal) infiltrate, and a variably cellular stroma composed of a spindle-shaped cells.

Sinonasal Teratocarcinosarcoma (Figs. 3-110 through 3-113)

Definition: High-grade malignant sinonasal tract neoplasm with combined histologic features of carcinosarcoma and teratoma.

Synonyms: Malignant teratoma; teratocarcinoma; teratoid carcinosarcoma

Clinical

- Uncommon tumor
- More common in men than in women; occurs over a wide age range with a median age of 60 years
- Generally presents as a rapidly growing neoplasm with symptoms primarily including nasal obstruction and epistaxis
- Most common site of involvement is the nasal cavity; other sites of involvement include the ethmoid and maxillary sinuses

- Radiology:
 - Nasal cavity mass or clouding/opacification of a sinus
 - Associated bone destruction may be seen
- No known cause

Pathology

Gross

- Friable to firm, red-brown mass

Histology

- All neoplasms are characterized by a combination of epithelial and mesenchymal tissue components and teratoid elements with heterogeneous or variegated architectural growth patterns.
- Epithelial components include:
 - Glandular or ductal structures lined by benign-appearing partly ciliated columnar epithelium
 - Nonkeratinizing immature (fetal-appearing) squamous epithelium with clear cytoplasm:
 - Important and characteristic histologic finding for the diagnosis
 - Supportive evidence of the teratoid nature of this neoplasm given its description in teratomas of other organ systems
 - Squamous epithelium without clear cells
 - Areas of squamous carcinoma and adenocarcinoma
 - Poorly differentiated malignant epithelial elements
 - Transitions among the above epithelial components can be seen.
- Mesenchymal components include:
 - Benign- and malignant-appearing fibroblasts or myofibroblasts
 - Rhabdomyosarcoma
 - Benign cartilage with an immature or “fetal” appearance and chondrosarcoma
 - Osteoid and/or osteosarcoma
- Teratoid components include:
 - “Fetal-appearing” clear cell squamous epithelium
 - Neuroepithelial component with neuroblastoma-like areas, neural rosettes, neurofibrillary matrix, and organoid structures
- No areas of seminoma, germinoma, choriocarcinoma, or embryonal carcinoma are present.
- Histochemistry:
 - Abundant glycogen as demonstrated by diastase-sensitive, PAS-positive material seen in clear cells
 - Mucin and PAS-positive material seen within the lumen and/or cytoplasm of the glandular component
- Immunohistochemistry: dependent on the cytologic components and includes:
 - Epithelial components: reactivity with cytokeratins, epithelial membrane antigen

Fig. 3-111. Sinonasal teratocarcinosarcoma.

The epithelial component may include (A) nonkeratinizing clear cell squamous epithelium (fetal type) and (B) dilated glandular space lined by an epithelium demonstrating a transition from a bland-appearing cuboidal and columnar epithelium (benign) to a cellular columnar epithelium with hyperchromatic, stratified nuclei (malignant). C, Adenocarcinoma associated with a malignant fibroblastic stromal component. D, Squamous cell carcinoma admixed with a malignant pleomorphic mesenchymal component.

Fig. 3-112. Sinonasal teratocarcinosarcoma.

A, Neurofibrillary matrix associated with an immature and undifferentiated small round cell infiltrate. **B**, Neural rosettes associated with a neurosarcomatous cellular infiltrate.

- Mesenchymal components: vimentin, desmin, actins, myoglobin, myf-4, S100 protein, BER-EP4
- Neuroepithelial/primitive cell components: CD99, S100 protein, chromogranin, CD57 (Leu-7), neuron specific enolase, glial fibrillary acidic protein (GFAP)
- No immunoreactivity for alpha-fetoprotein and human chorionic gonadotropin (HCG)

Differential Diagnosis

- Squamous carcinoma and variants thereof (e.g., adenosquamous carcinoma)
- Adenocarcinoma
- Olfactory neuroblastoma
- Sinonasal undifferentiated carcinoma
- Carcinoma ex-pleomorphic adenoma and carcinosarcoma
- Malignant mesenchymoma
- Ewing sarcoma family of tumors
- Rhabdomyosarcoma
- Craniopharyngioma
- Germ cell tumors including yolk sac tumor (endodermal sinus tumor) and choriocarcinoma:
 - May rarely occur as primary neoplasm in the upper aerodigestive tract (UADT)
 - Yolk sac tumors of the UADT tend to occur in children:
 - Associated with elevated serum alpha-fetoprotein

- Choriocarcinoma of the UADT tend to occur in adults:
 - Associated with elevated serum HCG
- Histology similar to occurrence in more usual (gonadal) sites
- Treatment and prognosis:
 - For yolk sac tumor:
 - If possible, complete surgical resection
 - Combination radiation and chemotherapy (platinum-based)
 - Distant visceral and nodal metastases occur.
 - For choriocarcinoma:
 - Chemotherapy for germ cell malignant tumors
 - Uncertain outcome

Treatment and Prognosis

- Aggressive therapy, including radical surgical extirpation and irradiation
- Highly malignant neoplasm with an average survival of <2 years
- Recurrence of tumor is common with extensive local invasion
- Tendency for extensive local invasion including soft tissues, bone, orbit, and central nervous system
- Metastatic disease occurs primarily to cervical lymph nodes.

Fig. 3-113. Sinonasal teratocarcinosarcoma.

Aside from a spindle cell (benign and/or malignant) stromal proliferation, the mesenchymal components of sinonasal teratocarcinosarcoma may include (A) immature cartilaginous nest; (B) chondrosarcoma; and (C) rhabdomyosarcoma including strap cells and identifiable cross striations.

SECONDARY TUMORS

(Fig. 3-114)

Definition: Tumors involving the sinonasal tract that originate from separate (noncontiguous) primary sites excluding hematolymphoid malignancies (i.e., lymphomas and leukemias).

Clinical

- Rare occurrence
- More common in men than in women; occurs over a wide age range
- Symptoms similar to primary sinonasal tumors:
 - Nasal obstruction, epistaxis, headache, pain, visual disturbances, facial swelling, cranial nerve deficits
- Metastatic tumors to the sinonasal tract may represent the initial manifestation of disease from an otherwise clinically occult primary tumor (e.g., renal cell carcinoma); more often, metastasis to the upper aerodigestive tract is part of widely metastatic disease.
- May be solitary or multifocal lesions
- Most common to maxillary sinus but also may involve multiple sinuses and the sphenoid sinus

Fig. 3-114. Metastatic renal cell carcinoma to the maxillary sinus.

A, The histology of this tumor including the presence of cell nests separated by fibrovascular stroma composed of cells with clear cytoplasm and distinct cell membranes with intraluminal red blood cells is unusual for a primary sinonasal tract tumor and should engender the consideration of a metastasis to this site from a separate (distant) primary tumor. This consideration was relayed to the clinicians, and in the patient work-up an occult primary renal tumor was found. The histology of the renal tumor and the sinonasal tumor were identical, and the diagnosis of a primary renal cell carcinoma metastatic to the sinonasal tract was made. Immunohistochemical findings of the sinonasal tract tumor (prior to the discovery of the primary renal tumor) included reactivity for **(B)** renal cell carcinoma (RCC) marker and **(C)** CD10 and **(D)** PAX8 (nuclear) supporting the diagnosis of metastatic renal cell carcinoma.

TABLE 3-13 Secondary Tumors to the Sinonasal Tract

Primary Tumor	Frequency	Immunohistochemistry*
Kidney	40%	CD10, RCC, PAX8 positive
Lung	9%	Napsin A, TTF-1 positive
Breast	8%	Mammaglobin, BRST-2 positive
Thyroid	8%	Thyroglobulin, TTF-1, PAX8 positive
Prostate	7%	Prostein, PSA, PSAP positive
Miscellaneous	28%	

*Markers in conjunction with light microscopy confirm diagnosis. CAIX, Carbonic anhydrase IX; PSA, prostate specific antigen; PSAP, prostatic acid phosphatase; RCC, renal cell carcinoma marker; TTF-1, thyroid transcription factor 1.

- Although virtually every conceivable malignancy may metastasize to the upper aerodigestive tract, the most common primary tumor metastatic to this region is renal cell carcinoma (Table 3-13).
- Differential diagnosis for metastatic renal cell carcinoma to the sinonasal tract includes:
 - Sinonasal renal cell-like adenocarcinoma (SRCLA):
 - Represents a rare sinonasal neoplasm, which is a histologic mimic of renal cell carcinoma (RCC) in patients without evidence of a primary RCC
 - More common in woman than in men (3:1); occurs over a wide age range from 22 to 69 years (mean 46 years)

- Histology:
 - Uniformly composed of clear cells forming solid or glandular patterns
 - Tumor cells are cuboidal to polyhedral; spindle-shaped cells may be present.
 - Bland cytomorphology lacking significant nuclear pleomorphism increased mitotic activity or necrosis; moderate nuclear pleomorphism may be present.
 - No perineural or lymph-vascular invasion
 - No evidence of squamous differentiation
- Histochemical staining:
 - Absence of epithelial mucin
- Immunohistochemistry staining:
 - Positive for CK7 (4/4), CK20 (focal 1/4), S100 (1/4), CD10 (1/2)
 - Negative for vimentin, RCC marker thyroglobulin, actin, calponin
- Treatment primarily with surgery with or without adjuvant radiotherapy (RT)
- All patients are disease free at 2, 4, 5, and 8 years after diagnosis.
- Difficulties in categorizing a given neoplasm within known primary tumors for a given site should prompt consideration for the possibility of metastatic disease originating from a distant site.
- Immunohistochemical staining is often required to confirm the diagnosis of a metastasis to the sinonasal tract (see Table 3-13).

Non-Neoplastic Lesions of the Pharynx

CLASSIFICATION OF NON-NEOPLASTIC LESIONS OF THE PHARYNX (Box 9-1)

BOX 9-1 Classification of Non-Neoplastic Lesions of the Pharynx, Including Naso-, Oro-, and Hypopharynx

Nasopharyngeal Cysts

- Rathke pouch cyst
- Tornwaldt cyst
- Dermoid cyst
- Retention cysts
- Others

Hamartomas, Choristomas, and Teratomatous Lesions

- Nasopharyngeal hamartoma
- Heterotopic CNS tissue
- Nasopharyngeal dermoid
- Lymphangiomatous polyp
- Salivary gland anlage tumor

Infectious and Related Diseases and Lesions

- Viral (HPV, EBV, HIV, CMV, HSV), including infectious mononucleosis, HIV-associated lymphoid hyperplasia of Waldeyer ring; others
- Fungal
- Bacterial including gonorrhea, syphilis, bacillary angiomatosis, others
- Protozoal
- Sarcoidosis
- Others

Reactive, Inflammatory, and Tumor-like Lesions

- Tangier disease
- Others

NASOPHARYNGEAL CYSTS

- Nasopharyngeal cysts are divided into congenital cysts and acquired cysts:
 - Congenital cysts of the nasopharynx include:
 - Rathke pouch cyst
 - Tornwaldt cyst
 - Dermoid cyst
 - Acquired cysts of the nasopharynx include:
 - Midline and lateral retention cysts

Rathke Pouch (Cleft) Cyst (Figs. 9-1 through 9-3)

Definition: Congenital cystic dilatation of Rathke cleft due to failure to obliterate the lumen between the anterior lobe of the pituitary and the pars intermedia.

Embryology and Anatomy

- Rathke pouch is an ectodermally derived outpocketing arising from the roof of the primitive oral cavity lying superior to the buccopharyngeal membrane that develops around the third week of gestation and grows toward the brain.
- Rathke pouch ultimately forms the anterior lobe of the pituitary gland.
- By the fifth week of gestation, this pouch has elongated and become constricted at its attachment to the oral epithelium and comes into contact with the infundibulum, which ultimately develops into the posterior lobe of the pituitary gland.
- The posterior part of Rathke pouch develops into the pars intermedia:
 - Lumen between the anterior lobe and the pars intermedia gradually obliterates; however, if the lumen does not close, a cleft is formed (Rathke cleft) that may become cystic, developing a Rathke cyst.

Clinical

- Rathke pouch cyst represents approximately 2% of all lesions of the sella turcica.
- Typically, Rathke pouch cyst is an asymptomatic, congenital lesion that is incidentally found in routine autopsies.
- Symptomatic cysts occur but are uncommon:
 - Symptomatic cysts are more common in women than in men and occur over a wide age range but are most common in the fourth decade of life.
 - Symptoms include headaches, visual disturbances, nausea, vomiting, pituitary-related abnormalities, including galactorrhea, amenorrhea, diabetes insipidus, acromegaly, and meningeal irritation.
 - Sudden onset of severe headache or sudden increase in headache severity may occur and has been associated with hemorrhage into the cyst, a

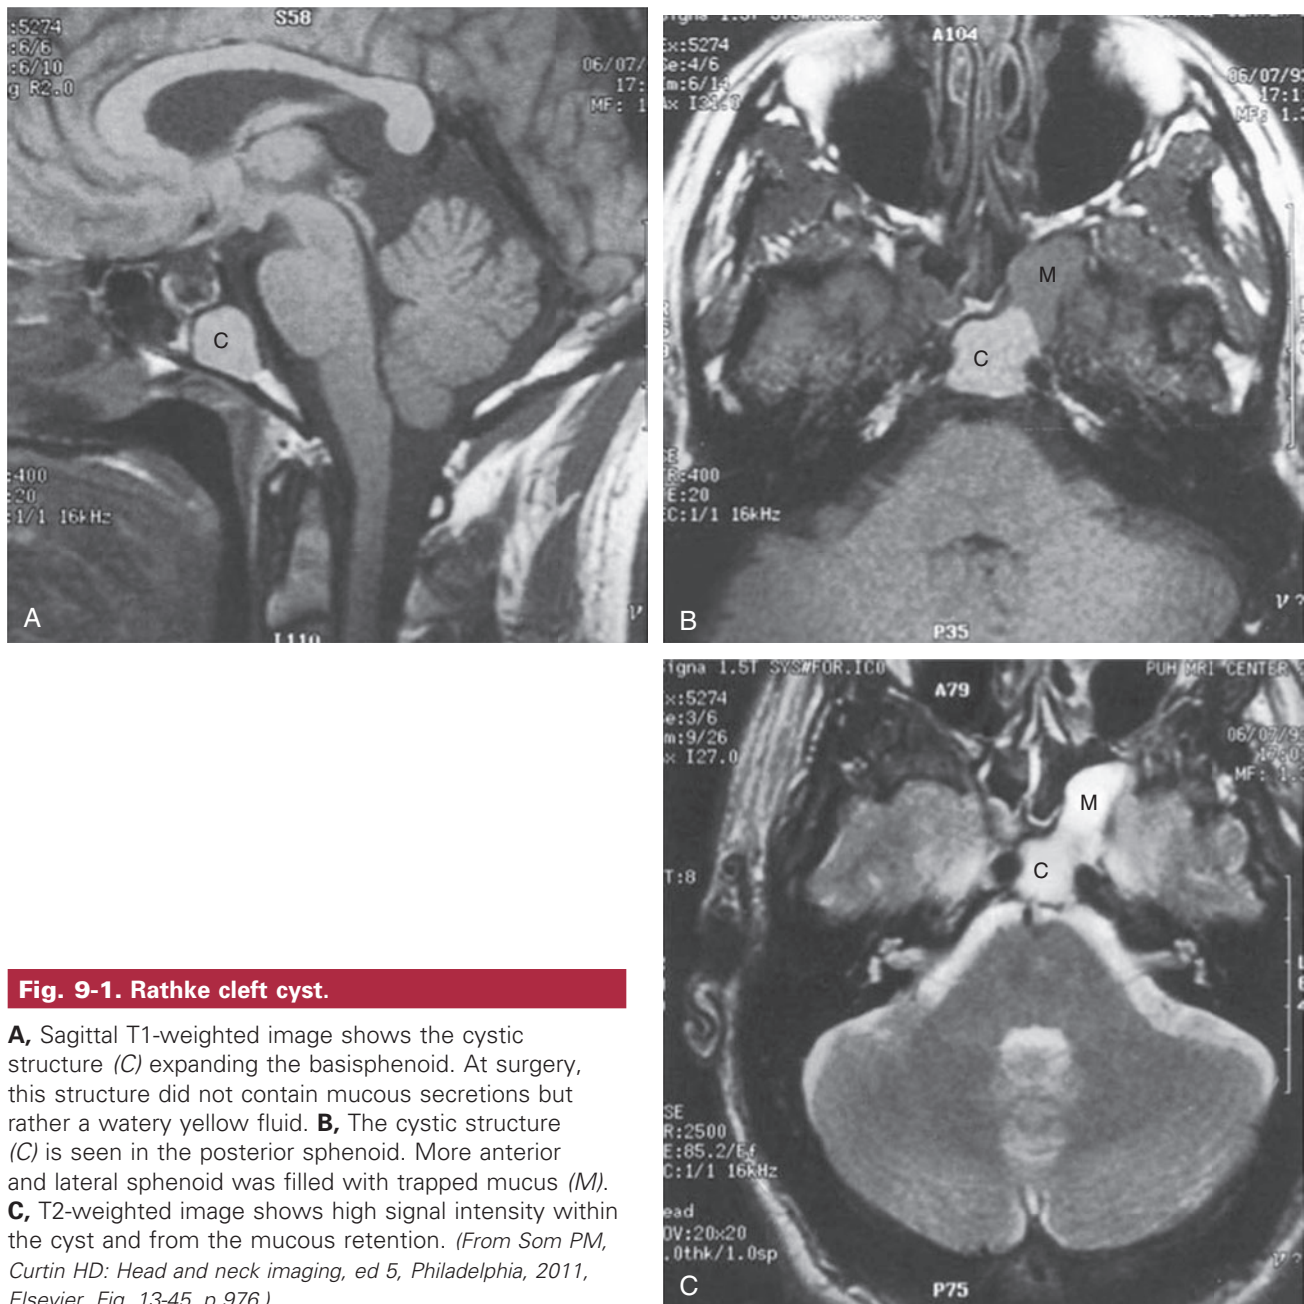

Fig. 9-1. Rathke cleft cyst.

A, Sagittal T1-weighted image shows the cystic structure (C) expanding the basisphenoid. At surgery, this structure did not contain mucous secretions but rather a watery yellow fluid. **B**, The cystic structure (C) is seen in the posterior sphenoid. More anterior and lateral sphenoid was filled with trapped mucus (M). **C**, T2-weighted image shows high signal intensity within the cyst and from the mucous retention. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 13-45, p 976.)

presentation that mimics the clinical syndrome of pituitary tumor apoplexy, leading to the designation of Rathke cleft cyst apoplexy.

- Increased serum prolactin has been reported in Rathke pouch cysts.
- Rare association with Klinefelter syndrome has been reported.
- Hybrid lesions, including Rathke cleft cyst and pituitary adenoma, have been reported.
- Radiology:
 - Well-circumscribed, round, or lobulated intrasellar mass:

- Wall of cyst is generally thin.
- Cyst content usually similar to cerebrospinal fluid
- More complex cysts show increased density with septa partitioning the cystic portion.
- Most lesions have intrasellar and suprasellar components although lesions confined to the sella turcica can be found, as well as suprasellar lesions and intrasphenoidal lesions may occur.
- Usually lacks associated calcifications:
 - Absence of calcifications assists in differentiating a Rathke pouch cyst from a

Fig. 9-2. Embryologic development of Rathke pouch cyst and Tornwaldt cyst.

A, Sagittal drawing of the developing pharynx. The level of the oropharyngeal membrane is shown. This membrane separates the ectodermally derived mucosa from the endodermally derived mucosa. The location of the developing notochord is shown in the mesoderm that will eventually become the clivus. **B**, Sagittal drawing shows the normal ventral migration of the notochord to touch the pharyngeal mucosa. **C**, Sagittal drawing shows Tornwaldt sinus or pit that develops if the notochord attaches to the pharyngeal mucosa and drags it dorsally as the notochord migrated back to its normal location. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 29-66, p 1791.)

Fig. 9-3. Rathke pouch cyst.

Pharyngeal submucosal cyst lined by a ciliated respiratory epithelium.

Pathology

Histology

- Cysts are lined by cuboidal to columnar epithelium with or without cilia; goblet cells can be found and foci of squamous epithelium may be present.
- Mineralization (calcifications), cholesterol granulomas, and xanthomatous cells can be found.
- Immunohistochemistry:
 - Epithelial cells are reactive for cytokeratins and epithelial membrane antigen (EMA) with variable reactivity for S100 protein, chromogranin, glial fibrillary acidic protein, and pituitary peptide markers.

Differential Diagnosis

- Rathke pouch cyst, which is localized to the area of the sella turcica, contrasts to Tornwaldt cyst located in the posterior pharynx.

- craniopharyngioma; craniopharyngiomas are characterized by the presence of calcifications.
- Rare examples of Rathke pouch cyst may be associated with mineralization.

Treatment and Prognosis

- Drainage of the cyst with partial removal of the cyst wall (for diagnosis) via a transsphenoidal approach is the preferred treatment.
- Endoscopic endonasal resection used as a safe and effective approach in treatment
- 5% recurrence rate has been reported.

Tornwaldt Cyst

(see Figs. 9-2 and 9-4)

Definition: Developmental anomaly of the posterior superior nasopharynx, in which there is persistence of the pharyngeal-to-notochord contact, creating a potential space into where there is in-growth of pharyngeal tissue.

Fig. 9-4. Tornwaldt cyst.

A, CT scan through the upper nasopharynx demonstrates a midline Tornwaldt cyst (*arrowheads*). Note that its density is similar to that of the surrounding muscle. The high density of this cyst is probably related to its high protein concentration. **B**, Sagittal T1-weighted MR scan through the upper nasopharynx demonstrates a high signal intensity Tornwaldt cyst (*c*). The high intensity is a result of the high protein concentration within the cyst. This shortens the T1 relaxation time sufficiently to produce an increase in intensity on T1-weighted images. **C**, Axial T1-weighted noncontrast MR image shows a well-delineated lesion (*arrow*) with increased signal intensity located within the nasopharynx. This was a Tornwaldt cyst. **D**, There is increased signal within the lesion on the T2-weighted sequence, which is consistent with the cystic nature of the mass. Note the internal septation present within the lesion (*arrow*). (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 29-68, p 1792.)

Synonyms: Pharyngeal bursa; Tornwaldt bursa; when infected this is referred to as Tornwaldt disease or syndrome; also spelled Thornwald cyst.

Embryology and Anatomy

- Pharyngeal bursa is a sac-like depression on the posterosuperior nasopharyngeal wall that forms around the sixth week of gestation when the cephalic portion of the notochord comes into close contact with the foregut:
 - Contact between the pharynx and the notochord is usually transient but may persist in adults, in whom the pharyngeal respiratory epithelium may grow, creating a potential space that may be walled off, creating the Tornwaldt cyst.

Clinical

- Tornwaldt cyst is uncommon.
- No gender predilection
- These cysts may occur at any age, although most are diagnosed in the second to fourth decades of life.
- They may be asymptomatic, but when infected, symptoms include drainage into the nasopharynx of purulent material; in addition, symptoms may include headaches, otalgia, and fullness of the ear, halitosis, and neck soreness or stiffness.
- Cysts are located in the midline of the posterior nasopharyngeal wall but may be found slightly off midline:
 - Usually extends upward and backward toward the occipital bone
 - Tornwaldt cyst lies caudal to the location of Rathke cleft cyst.
- Endoscopic appearance of these lesions is that of a submucosal, firm, and smooth mass; adjacent mucosa may be erythematous.
- Radiology:
 - Appear as a mass high on the posterior nasopharyngeal wall; air may be seen in the tract extending from the midline posterior nasopharynx toward the occipital tubercle.
 - On CT scan, the cyst may contain fluid of similar density as cerebrospinal fluid and does not enhance after contrast; calcifications may be identified.

Pathology

Histology

- Cysts are submucosal; the lining includes a ciliated respiratory epithelium; squamous metaplasia is present in the setting of an infected cyst.

Differential Diagnosis

- Rathke pouch cyst, which is localized to the area of the sella turcica, contrasts to Tornwaldt cyst located in the posterior pharynx.

Treatment and Prognosis

- Surgical excision is the preferred treatment; incomplete excision will result in recurrence.
- Antibiotic therapy is used preoperatively for patients with infected cysts.

Other Nasopharyngeal Cysts

- Acquired retention cysts of the nasopharynx of seromucinous gland origin, as well as lymphoid crypt origin, can occur in midline or lateral locations.

PHARYNGEAL HAMARTOMAS, CHORISTOMAS, AND TERATOMATOUS LESIONS

Definitions

Hamartoma: Non-neoplastic developmental anomaly caused by excessive growth of normal cells and/or tissue indigenous to its site of occurrence. Hamartomatous lesions may occur in all head and neck sites but tend to predilect to the nasal cavity, paranasal sinuses, and the nasopharynx.

Choristoma (heterotropia, ectopia, aberrant rest): Non-neoplastic developmental anomaly of essentially normal tissue but with the tissue elements being foreign to its anatomic location

Nasopharyngeal Hamartoma

Clinical

- Uncommon lesion
- Reports of nasopharyngeal hamartomas are often included with nasal hamartomas, so a true incidence of hamartomas exclusively limited to the nasopharynx cannot be determined.
- No gender predilection; occur in adults and in children
- In adults, the clinical presentation may include nasal obstruction, difficulty breathing, post-nasal drainage, and epistaxis.
- In pediatric patients, the clinical presentation may include noisy breathing, stridor, feeding difficulties, and transient cyanosis.

Pathology

Gross

- Polypoid to cauliflowerlike, circumscribed, and lobulated masses partially or completely filling the nasopharynx and measuring from 1 to 4 cm in greatest dimension.

Histology

- May be composed of epithelial and/or mesenchymal components:
 - Epithelial hamartoma:
 - Minor salivary gland elements (seromucous glands, ducts, acini)
 - Epithelium (squamous and columnar cells)
 - Mesenchymal components:
 - Blood vessels, lymphoid tissue, fibrous stroma
- Metaplastic components such as bone may be present.

NOTE: The epithelial hamartomas may be histologically identical to the respiratory epithelial adenomatoid hamartoma and seromucinous hamartoma of the sinonasal tract (see Section 1 for more complete discussion).

Differential Diagnosis

- Teratoma
- Epithelial neoplasms:
 - Adenocarcinoma
 - Papilloma, carcinoma
- Mesenchymal neoplasms:
 - Hemangioma, angiosarcoma, others

Treatment and Prognosis

- Simple excision is curative.

Pharyngeal/Nasopharyngeal Central Nervous System Heterotopias

Definition: Presence of central nervous system (CNS) tissue as a mass lesion in the nasopharynx without connection to the cranial cavity.

Clinical

- Rare lesion that may occur in association with congenital anomalies

Pathology

Histology

- Histology of these lesions is similar to heterotopic CNS tissue of the nasal cavity, but in contrast to the nasal lesions, those of the nasopharynx may include the presence of ependymal elements as well as intracytoplasmic melanin.

Treatment and Prognosis

- Simple excision is curative.

Nasopharyngeal Dermoid

(Fig. 9-5)

Definition: Developmental (congenital) anomaly predominantly composed of ectodermal and mesodermal tissue but lacking endodermal-derived tissues.

NOTE:

- Absence of endodermal-derived structures and presence of limited heterogeneity of tissue types argue against inclusion as a teratoma.
- The fact that these lesions contain skin, a tissue type not normally found in the nasopharynx, suggests that these lesions may be better classified as a choristoma than a hamartoma, and possibly of first branchial arch origin; some authors argue that these lesions are best classified as a subset of benign teratoma.

Synonym: Hairy polyp

Fig. 9-5. Nasopharyngeal dermoid (hairy polyp).

A, Polypoid solid lesion with identifiable hairs on the surface. **B,** Histology includes a combination of ectodermal and mesodermal tissues including skin (keratinizing squamous epithelium), cutaneous adnexal structures, including hair follicles and sebaceous glands, and cartilage.

Clinical

- Predilection for female infants with majority of the cases occurring in the infantile period
- Symptoms include difficulties in breathing, swallowing, or sucking.
- May arise in other areas of the pharynx including oropharynx, as well as in association with the eustachian tube and the middle ear

Pathology**Gross**

- Polypoid, predominantly solid but partially cystic lesions; may be pedunculated or sessile

Histology

- Combination of various ectodermal and mesodermal tissues, including:
 - Skin (keratinizing squamous epithelium) and cutaneous adnexa
 - Cartilage, bone, muscle (striated or smooth), fibrous tissue, mature adipose tissue, and vascular tissue
 - Lymphoid aggregates may be identified.
- Polypoid lesions covered by skin with identification of hair follicles and sebaceous glands within the submucosa and identification of elastic cartilage:
 - These histologic findings identified in a lesion of the ear have suggested to some authors that these lesions are of branchial cleft origin, representing congenital accessory auricles akin to accessory tragus.

Differential Diagnosis

- Teratoma:
 - Absence of endodermally derived tissue and absence of the wide variety of tissue types usually seen in teratoma will allow for distinguishing these lesions.

Treatment and Prognosis

- Simple surgical excision is curative.

Lymphangiomatous Polyp of the Tonsil (Figs. 9-6 and 9-7)

Definition: Non-neoplastic developmental lesion composed of tissue elements native to the nasopharynx and categorized as a hamartoma.

Synonym: Lymphoid polyp

Clinical

- Uncommon lesion
- No gender predilection; occur over a wide age range from the first decade to the seventh decade with a mean age of occurrence at 25 years

Fig. 9-6. Tonsillar lymphangiomatous polyp.

Pedunculated polyps with solid (A) and partially cystic (B) appearance.

- Clinical presentation includes dysphagia, sore throat, and the sensation of a mass lesion in the throat:
 - Symptoms may be present from a few weeks to years.
- Majority are of palatine tonsil origin but occasionally may originate from the nasopharynx or from the nasopharyngeal tonsil (i.e., adenoids):
 - Unilateral lesions without side predilection
- Clinical examination, many of these lesions are felt to be neoplasms

Pathology**Gross**

- The majority are polypoid or pedunculated with a smooth external surface, spongy to firm consistency that on cut section have a white, tan, or yellow

Fig. 9-7. Tonsillar lymphangiomatous polyp.

Polypoid lesions in which the surface squamous epithelium is rounded (**A**) or bosselated (**B**) with a submucosal proliferation of dilated lymphatic vascular channels and lymphoid cell infiltrate with clear demarcation from the surface epithelium (**A**) intimate association with the surface epithelium (**B**); **C** and **D**, Lymph-vascular channels (which are endothelial cell-lined) vary in size and shape and are variably associated with a fibrous connective tissue component and lymphocytic cell infiltrate.

appearance measuring from 0.5 to 3.8 cm in greatest dimension.

- Some lesions are sessile.

Histology

- Covered by squamous or respiratory epithelium composed of a submucosal proliferation of dilated lymphatic vascular channels and varying amounts of fibrous connective tissue.
- Vascular components are thin-walled and usually contain proteinaceous fluid and mature lymphocytes.
- In addition, mature adipose tissue may be present, and prominent fibrosis may dominate in any given lesion.
- Some lesions may be exclusively or predominantly papillary with a lymphoid and edematous stroma.
- Additional findings that can be identified include epithelial hyperplasia, hyperkeratosis, and dyskeratosis without epithelial dysplasia and nested epitheliotropism; the latter includes the presence of mature lymphocytes packed into rounded intramucosal spaces.
- Special stains are not required for the diagnosis.
- Immunohistochemistry:
 - Vascular endothelial markers, including Factor VIII-related antigen, CD31 and CD34, as well as podoplanin (D2-40), present in the endothelial and subendothelial cells of the vascular channels.
 - Smooth muscle actin reactivity can be found within the vascular walls.
 - Lymphoid component shows reactivity for B-cell (CD20) and T-cell (CD3) markers.

Differential Diagnosis

- Nasopharyngeal angiofibroma:
 - Occurs in adolescent males
 - Typically presents with epistaxis due to its rich blood supply that often attains large sizes with extensive growth and even bone erosion
 - Histologically have a cellular stroma composed of stellate fibroblasts and staghorn-shaped, thin-walled vascular structures, the latter typically lacking or with an attenuated smooth muscle component
 - Fibroblastic cells are immunoreactive for β -catenin
 - In contrast to nasopharyngeal angiofibromas, the lymphangiomatous polyps may occur in women and tend to have a relatively paucicellular fibrous stroma with a prominent lymphoid component.
- Fibroepithelial polyps
- Papillomas
- Epithelial neoplasms characterized by the presence of an exophytic surface epithelial proliferation of multilayered bland epithelial cells and lacking an associated lymphoid component
- Majority of squamous papillomas lack surface keratin, although occasionally prominent (hyper) keratosis may be identified
- Rare examples of Schneiderian-type papillomas may occur in the pharynx (oro- and nasopharynx), but the histology of the lesions contrast so distinctly

from the lymphangiomatous polyps, making differentiation straightforward.

- Lymphangioma:
 - Neoplasm of endothelial-lined lymphatic spaces that are histologically characterized by the presence of widely dilated and irregularly appearing vascular channels, features not usually associated with lymphangiomatous polyps

Treatment and Prognosis

- Simple surgical excision usually in the form of a unilateral tonsillectomy is curative.

Salivary Gland Anlage Tumor (SGAT) (Fig. 9-8)

Definition: Benign tumor with mixed epithelial and mesenchymal elements recapitulating early stages in the embryology of salivary glands between the fourth and eighth weeks of development.

Synonym: Congenital pleomorphic adenoma

Clinical

- Rare lesion with fewer than 20 cases reported in the literature
- Male predilection; usually presents in immediate neonatal period or in early infancy (by age of 6 weeks)
- Symptoms include respiratory distress, nasal airway obstruction, and/or feeding difficulties.

Fig. 9-8. Salivary gland anlage tumor (SGAT).

A, At low magnification, SGAT is characterized by multiple submucosal solid nodules separated by less cellular stroma and network of delicate linear and branching small duct-like structures and nests of solid or cystic squamous epithelium with variable (internodular) fibromyxoid stroma. **B**, Duct-like structures and squamous nests (with and without keratinization) are more prominently seen toward periphery of (and in between) the cellular stromal nodules.

Continued

**Fig. 9-8, cont'd**

C, Focally, duct-like structures may be connected to surface epithelium. **D**, Cellular nodule composed of fusiform cells forming short fascicles or trabecular growth pattern. **E**, Stromal cells are composed of ovoid to spindle-shaped nuclei with uniform dispersed nuclear chromatin and eosinophilic cytoplasm with indistinct cell borders; a mitotic figure is present (*arrow*). **F**, Cytokeratin (AE1/AE3) immunoreactivity is present in the epithelial components (squamous nests and duct-like structures) and mesenchymal component. **G**, Variable p63 reactivity is present in the epithelial components (squamous nests and duct-like structures) and mesenchymal component.

- Often located at or near midline in the nasopharynx:
 - Uniform midline presentation is a feature in common with other developmental anomalies in the head and neck region, including:
 - Dermoid sinus, nasal glioma, and thyroglossal duct cyst
- Imaging by CT and MRI helpful in determination of size of the mass and relationship to surrounding anatomic structures.

Pathology

NOTE: There is uniformity in the gross and microscopic features from case to case.

Gross

- Pedunculated polyp measuring from 1.5 to 4 cm
- May be ulcerated with hemorrhage and necrosis

Histology

- Surface lined by a nonkeratinizing squamous mucosa
- At low magnification, multiple submucosal solid nodules separated by less cellular stroma and network of delicate linear and branching small duct-like or glandular structures and nests of solid or cystic squamous epithelium set in a variably fibromyxoid stroma:
 - Duct-like structures and squamous nests (with or without keratinization) more prominent toward periphery of the more cellular stromal nodules but may be present within more central aspects of the cellular stromal nodules
 - Duct-like structures may be connected to surface epithelium in areas.

- Epithelial units within internodular stroma blend into cellular nodules.
- Cellular nodules are composed predominantly of fusiform cells forming short fascicles or trabecular structure:
 - Stromal cells characterized by ovoid to spindle-shaped nuclei with uniform dispersed nuclear chromatin and eosinophilic cytoplasm with indistinct cell borders
 - Mitotic figures may be present.
- Extensive hemorrhagic necrosis may be present:
 - Likely the result of torsion
- Rarely, bone formation may be present.
- Immunohistochemistry:
 - Epithelial components:
 - Reactive for cytokeratins (pancytokeratins, CK7), p63
 - EMA restricted to tubular structures
 - Mesenchymal components:
 - Reactive for vimentin, cytokeratins (AE1/AE3, CAM 5.2, CK7, OSCAR), p63, and muscle-specific actin
 - Nonreactive for S100 protein and GFAP
 - Variable proliferation rate (by Ki67 staining) from tumor to tumor and even within the same tumor from as low as 1% to as high as 20% to 30%
 - Consistent diffuse and widespread reactivity for salivary gland amylase

Treatment and Prognosis

- Simple excision (polypectomy) is curative.
- No reported recurrences

INFECTIOUS DISEASES OF THE NASOPHARYNX AND OROPHARYNX

- Infections of the pharynx include bacterial, viral, fungal, mycobacterial, protozoal, and other infectious agents.
- Breadth of infectious diseases of these sites is extensive, and this section focuses on select infectious diseases of these anatomic sites.

TONSILLITIS

Definition: Primary (bacterial) infection of the palatine tonsils.

Synonyms: Chronic tonsillitis, hyperplastic tonsils; tonsils with benign lymphoid hyperplasia; chronic fibrosing tonsillitis

Clinical

- Tonsillitis is one of the more common diseases of the head and neck.
- No gender predilection
- Patients with acute exudative tonsillitis are typically young and include children, teenagers, and young adults.
- Symptoms include rapid onset of fever and localized pain to the tonsillar region (odynophagia) and malaise; associated referred pain to the ear (otalgia) and dysphagia may be present.
- Involvement of the adjacent pharyngeal wall as well as the adenoids is not infrequently seen.
- Incubation periods tend to be short (i.e., days) and associated lymphadenopathy is common.

- Etiologic agent in this setting is typically a bacterial infection:
 - Most often group A β -hemolytic streptococci, *Haemophilus influenzae*, *Staphylococcus aureus*
 - Less common etiologic agents include *Corynebacterium diphtheriae* (diphtheria) and *Bordetella pertussis* (whooping cough)
 - Viruses may cause tonsillitis, including adenoviruses and Epstein-Barr virus (EBV).
- On examination the tonsils (and/or adenoids) are enlarged, hyperemic, and covered by a yellow exudate.

Pathology

Histology

- An acute inflammatory infiltrate of the tonsils is hardly ever seen in surgical pathology material.
- More typically the tonsils, as well as adenoids, show the presence of benign lymphoid hyperplasia characterized by enlarged and irregularly shaped germinal centers that include the presence of tingible body macrophages and with identifiable mantle lymphocytes.
- Often there is polarity (i.e., increased cellularity) of the mantle cell lymphocytes toward the site of the antigenic stimulation; the latter usually is from the mucosa surface such that there is a mantle lymphocyte expansion on the side of the germinal center that is oriented toward the surface.
- In association with the benign lymphoid hyperplasia there often is interfollicular expansion with increased mature plasma cells. In the presence of a viral infection a prominent immunoblastic proliferation may be seen.
- Viral inclusions may be identified:
 - EBV infection may result in the clinical and histologic features of infectious mononucleosis (see below).
- Fibrosis may or may not be present.
- Depending on the time frame, the histology associated with peritonsillar abscess may include the presence of pools of neutrophils (which is the histologic definition of an abscess) or chronic inflammatory cells or both.
- Actinomycotic organisms in the form of “sulfur granules” are saprophytes and normally found in the tonsillar crypts; therefore the presence of these microorganisms in the tonsillar crypts is not an indication of an infection:
 - To consider a diagnosis of an actinomycotic infection, the microorganism must be identified within the tonsillar parenchyma (see Section 4, Neck).
 - Similarly, the presence of neutrophils within the tonsillar crypt is not an indication of acute tonsillitis; neutrophils must be present in the

parenchyma to consider the diagnosis of acute tonsillitis (or adenoiditis).

- Surface epithelium is usually intact and unremarkable but may be eroded (particularly in resolving acute tonsillitis) or may rarely show papillary hyperplasia that histologically includes the presence of surface papillary projections formed by hyperplastic lymphoid tissue.

Differential Diagnosis

- Usually the diagnosis of tonsillitis is straightforward.
- HIV-infection of the tonsils (and adenoids)
- Other specific infectious diseases
- Neoplasm (e.g., lymphoma)

Treatment and Prognosis

- Treatment for bacterial infection involves administration of antibiotics:
 - Penicillin is primary antibiotic used in treatment.
 - Broad-spectrum cephalosporins (e.g., cefuroxime axetil) can be used for primary treatment and can be effective for persistent infection.
 - Patients allergic to penicillin can be treated with azithromycin.
- The issue relative to surgery is controversial:
 - Some patients have repeated (recurrent) attacks of tonsillitis, and these patients may be antibiotic-resistant, resulting in the recurrent attacks. For these (and perhaps other) patients surgical management may be required.
 - Patients who experience at least three episodes of tonsillitis in 3 consecutive years, five episodes in 2 years, or seven episodes in 1 year may benefit from surgery.
- Complications of surgery include postoperative bleeding, which can occur in up to 3% of patients:
 - Primary postoperative bleeding occurs within the first 24 hours after surgery and usually is related to the surgical procedure.
 - Secondary or delayed postoperative bleeding occurs more than 24 hours after surgery and usually is related to loosening of the sutures of infection.

PERITONSILLAR ABSCESS

Definition: Collection of purulent material behind the posterior capsule of the tonsil.

Synonym: Quincke

Clinical

- No gender predilection; primarily occurs in adolescents and adults
- Approximately one third of patients have a prior history (one or more episodes) of tonsillitis.

- Development of abscess occurs over time with gradually increasing pharyngeal (throat) discomfort occurring over days with subsequent dysphagia, odynophagia, ipsilateral otalgia, “hot potato” voice, trismus, and fever.
- Etiologic agents most often include α - and β -hemolytic streptococci and anaerobic bacteria (mainly *Bacteroides* spp. and *Fusobacterium nucleatum*).
 - Due to the prior utilization of antibiotics, culture-negative peritonsillar abscess may occur in up to 40% of cases.
- On examination the tonsils are enlarged and bulging with deviation of the uvula and soft palate:
 - Often bilateral
 - Abscess typically located in the superior pole of the tonsils
 - Cervical adenopathy may be present.
- Radiology:
 - CT scan useful in localizing the abscess and confirming the diagnosis

Pathology

Histology

- Large (confluent) pools of neutrophils and/or chronic inflammatory cells in peritonsillar soft tissues

Differential Diagnosis

- Peritonsillitis:
 - Presence of acute and chronic inflammation with granulation tissue
 - In contrast to peritonsillar abscess, there is no pooling of inflammatory cells.

Treatment and Prognosis

- Conservative management including analgesics, antibiotics, fluids, incision, and drainage:
 - Incision and drainage are needed for:
 - Diagnosis and in excluding the possibility of a neoplastic process
 - Gathering material for culture and antibiotic sensitivity
- Tonsillectomy selectively used
- Conservative management is effective therapy with low recurrence rates (5% to 15%).
- Complications if unrecognized and/or untreated or inappropriately managed may include:
 - Extension of abscess into parapharyngeal space potentially into the wall of the carotid artery
 - Extension of abscess superiorly to the base of skull and/or into the cranial cavity
 - Extension inferiorly to the hypopharynx (piriform sinus) with obstruction of and possible rupture into the airway
 - Extension into the mediastinum via the carotid sheath or retropharyngeal space

VIRAL DISEASES

- Numerous viral diseases may potentially infect sites in the nasopharynx and oropharynx.
- This section is limited to the more common types of viral infections that may be seen in these locations.

Human Papillomavirus (HPV)-Related Diseases

- HPV represents a large group of small, double-stranded circular DNA viruses.
- HPV is strongly epitheliotropic.
- HPV is a sexually transmitted disease.
- Non-neoplastic diseases associated with HPV include (but may not be limited to):
 - Verrucae (verruca vulgaris [wart], condyloma acuminatum)
 - Focal epithelial hyperplasia (Heck disease)
- HPV is also associated with epithelial neoplasms, including benign and malignant neoplasms:
 - Squamous papilloma:
 - Associated with low-risk viruses, including types 6, 11
 - Oropharyngeal carcinomas (for more complete discussion see next chapter):
 - Associated with high-risk viruses, including type 16, 18
 - Active role of HPV may be as a promoter in the multistep process of carcinogenesis in squamous cells of the upper aerodigestive tract:
 - Two viral oncoproteins of high-risk HPV, E6 and E7, promote tumor progression by inactivation of p53 and retinoblastoma tumor suppressor gene products, respectively.
 - These viral oncoproteins are capable of disrupting the cell-cycle regulatory pathways in the genetic progression to SCC.
 - Dysfunction of the retinoblastoma gene product results in abnormal cell proliferation and the development of malignant tumors.
 - Types of oropharyngeal carcinomas associated with HPV:
 - Nonkeratinizing carcinoma
 - Variants of squamous cell carcinoma, including:
 - ◻ Basaloid squamous cell carcinoma
 - ◻ Verrucous carcinoma
 - ◻ Papillary squamous cell carcinoma
 - ◻ Spindle cell squamous carcinoma
 - ◻ Adenosquamous carcinoma
 - Small cell neuroendocrine carcinoma
- Oropharyngeal carcinomas, including base of tongue and tonsil strongly associated with HPV infection
- Histologically, a feature associated with HPV infection are koilocytes characterized by the presence of cells with condensed, pyknotic (“raisin-shaped”)

nuclei with perinuclear clear areas referred to as halos; binucleate and multinucleate cells may be present.

- Immunohistochemistry:
 - Immunomarkers are available for identification of HPV, including p16.
- Cytogenetics and molecular genetics:
 - Detection of HPV by using labeled probes to detect HPV RNA and DNA, as well as in situ polymerase chain reaction, has increased the detection of HPV.
 - HPV-16 is strongly associated with oropharyngeal carcinomas, and integration has been shown to be tightly coupled to the neoplastic process.

Cytomegalovirus and Herpesvirus

- See Section 2, Oral Cavity.

Epstein-Barr Virus–Related Diseases

- Epstein-Barr virus (EBV) is an enveloped icosahedral herpesvirus with double-stranded linear DNA.
- EBV is strongly tropic for B-lymphocytes and also is tropic for T-lymphocytes.
- Detection can be achieved by in situ hybridization for Epstein-Barr–encoded RNA (EBER).
- Non-neoplastic diseases associated with EBV include (but are not limited to):
 - Infectious mononucleosis
 - T/NK-cell chronic active EBV infection (CAEBV)
 - Post-transplantation lymphoproliferative disease (PTLD):
 - EBV is an important pathogen in recipients of solid organ transplants (SOT).
 - EBV disease and its associated PTLD are more frequently seen when primary EBV infection occurs after transplant, a common scenario in pediatric SOT recipients.
 - Oral hairy leukoplakia: see Section 2, Oral Cavity
 - Possible role for EBV has been suggested in chronic inflammatory/autoimmune diseases, such as rheumatoid arthritis and systemic lupus erythematosus, as well as in multiple sclerosis (MS):
 - Infectious mononucleosis has been shown to increase the risk of developing MS later in life.
 - EBV seroprevalence rates are higher in MS as compared with controls, in adult as well as in pediatric MS patients.
 - EBV antibody titers and EBV-specific T-cells are increased in MS patients as compared with healthy individuals.
 - CNS B-cells of MS patients have been reported to harbor EBV.
- There is increasing evidence that viruses may play a role in MS pathogenesis, acting as environmental triggers, but it is not known if any single virus is causal, or rather several viruses can act as triggers in disease development, including EBV and human herpesvirus 6 (HHV-6).
- EBV is also associated with neoplastic proliferations, including:
 - Epithelial malignancies:
 - Nasopharyngeal carcinoma, nonkeratinizing differentiated and undifferentiated types
 - Lymphoepithelial-like carcinoma (e.g., salivary gland, others)
 - Gastric carcinoma
 - Hematolymphoid malignancies:
 - Nasal-type NK/T-cell lymphoma
 - Burkitt lymphoma:
 - Occurs in approximately 30% to 40% of sporadic cases
 - Hodgkin lymphoma
 - Central nervous system lymphoma
 - Lymphomatoid granulomatosis
 - Aggressive NK-cell leukemia/lymphoma
 - T-cell lymphoproliferative disorders of childhood:
 - Hydroa vacciniforme-like lymphoma
 - Systemic EBV-positive T-cell lymphoproliferative disease
 - EBV-positive diffuse large B-cell lymphomas of the elderly
 - Diffuse large B-cell lymphoma associated with chronic inflammation
 - Pyothorax-associated lymphoma
 - Angioimmunoblastic T-cell lymphoma
 - AIDS-related lymphomas
 - Primary effusion lymphoma:
 - Type of diffuse large B-cell lymphoma occurring in HIV-infected patients consistently associated with HHV8 and commonly coinfecting by EBV
 - Sarcomas:
 - Leiomyosarcoma

Infectious Mononucleosis (IM) (Fig. 9-9)

Definition: IM is a systemic, benign, self-limiting infectious lymphoproliferative disease primarily caused by but not limited to Epstein-Barr virus (EBV) infection.

Pathogenesis

- EBV penetrates the nasopharyngeal epithelium and lymphoid tissues infecting B-lymphocytes.
- EBV enters B-lymphocytes through the CD21 molecule (attaches to C3d complement receptor) on the

Fig. 9-9. Infectious mononucleosis.

A and **B**, Excised tonsil showing distortion and partial effacement of tonsillar architecture with preservation of germinal centers with interfollicular (cellular) expansion. **C** and **D**, Interfollicular areas include a proliferation of immunoblasts, plasma cells, Reed-Sternberg-like cells, and lymphocytes showing marked nuclear atypia with prominent nucleoli, increased mitotic activity (*arrow*) that may include atypical forms and necrosis (confluent foci and individual cell). Out of context with the clinical history and laboratory findings these histologic features suggest a possible diagnosis of malignant lymphoma. **E**, Immunoreactivity is present for *left* B-cell markers (CD20) and *right* T-cell markers (CD3). **F**, Split field showing the atypical lymphoid proliferation (*left*) with immunoreactivity for EBV latent membrane protein (*right*).

Continued

Fig. 9-9, cont'd

G, In situ hybridization for Epstein-Barr encoded RNA (EBER) is positive.

surface of B cells or nasopharyngeal epithelial cells and enters these cells.

- EBV infects B-cells and elicits humoral and cellular immune responses, inducing the formation of new antigens, including:
 - Viral capsid antigen (VCA)
 - Membrane antigen (MA)
 - Early antigen (EA), including two subtypes:
 - Diffuse (EA-D)
 - Restricted (EA-R)
 - Epstein-Barr nuclear antigen (EBNA)
 - Lymphocyte-detected membrane antigen (LYDMA)
- Earliest phase of disease characterized by infection of B-cells that proliferate, develop neo-antigens, circulate, stimulate immune response, and synthesize immunoglobulin.
- VCA, EA, and EBNA are the viral protein most important for serodiagnosis in immunocompetent patients.

Clinical

- No gender predilection; may occur in all age groups but primarily affects adolescents and young adults
- EBV is estimated to cause from 80% to 95% of the cases of infectious mononucleosis.
- Clinical presentation of EBV-associated IM includes:
 - Acute pharyngotonsillitis with patients experiencing sore throat, fever, and malaise
 - Lymphadenopathy and hepatosplenomegaly with chemical evidence of hepatitis may represent the systemic manifestations of the disease.
 - Pharyngotonsillitis is often severe and may be exudative; lymphadenopathy commonly affects

posterior cervical lymph nodes, but anterior and posterior nodes may be involved.

- A prodromal period of from 2 to 5 days consists of malaise and fatigue and frequently occurs prior to the onset of the full syndrome.
- Diagnosis of infectious mononucleosis is established in a patient with typical clinical presentations and appropriate laboratory findings (see below); tissue confirmation of the diagnosis is usually not required and it is in the atypical case where the patient presents with adenotonsillar and/or lymph node enlargement without fever, sore throat, or splenomegaly that a biopsy may be needed to establish a diagnosis and rule out a malignant process.
- Laboratory findings in IM include:
 - Absolute lymphocytosis with more than 50% lymphocytes in a total leukocyte population of more than 5000/mm³
 - Prominent atypical lymphocytes (Downey cells), which are often more than 10% of the total leukocyte count (the atypical lymphocytes in the peripheral blood are thought to represent mostly activated T-lymphocyte populations in response to B-cell infection)
 - Mild to moderate elevations of liver enzymes, including aspartate and alanine aminotransferase
 - Diagnosis can be confirmed by the demonstration of serum antibodies to horse red cells (positive Mono-Spot test) or sheep erythrocytes (positive Paul-Bunnell heterophile antibody test)
 - Of the many patients in the United States with typical clinical features of IM, 70% or more have a positive heterophile antibody test identifying EBV as the cause.
 - Of the 30% without heterophile antibody, about 50% are IgM-VCA positive, also verifying EBV infection.
 - Patients who consistently prove to be heterophile antibody or Mono-Spot negative, serodiagnosis is invaluable and includes:
 - An appreciable serum response to EBV viral capsid antigen (VCA) with IgM and IgG antibodies at the time of clinical presentation
 - At presentation or shortly thereafter, many infected patients will develop antibodies to early antigen complex (EA).
 - During the early phase of primary infection, antibodies to EBV nuclear antigens (EBNA) are usually not demonstrable.
 - IgM antibodies to VCA disappear within 2 to 3 months following infection; antibodies to EA disappear within 2 to 6 months following infection; IgG antibodies to VCA and anti-EBNA antibodies persist for life and are indicative of a chronic carrier state.

- In immunocompromised patients, serologic tests are of limited value:
 - Direct detection methods considered more reliable:
 - EBV viral load by PCR better tests in immunocompromised patients
- Other microorganisms associated with mononucleosis-like syndromes include:
 - Cytomegalovirus (CMV), *Toxoplasma gondii*, rubella, hepatitis A virus, and adenoviruses
 - In patients with IM exhibiting the typical clinical presentation and hematologic findings but who are heterophile antibody negative:
 - Patients may still have EBV antibody-positive but heterophile-negative IM.
 - CMV is the most common cause of heterophile-negative IM.
 - Non-EBV infectious agents causing infectious mononucleosis are not associated with a positive heterophile antibody test and Mono-Spot test.

Pathology

Gross

- Moderate to severe pharyngitis may be seen characterized by marked swollen and enlarged tonsils covered by dirty gray exudates.
- Tender lymphadenopathy, particularly of the posterior cervical lymph nodes, occurs.

Histology

- At low magnification, there is distortion and/or partial effacement of the nodal/tonsillar architecture with reactive follicular hyperplasia characterized by enlarged and irregularly shaped germinal centers.
- There is expansion of the interfollicular areas with polymorphous proliferation of small lymphocytes, transformed lymphocytes, immunoblasts, plasma cells, and Reed-Sternberg-like cells:
 - Lymphocytic and immunoblastic proliferation often displays marked cytologic atypia with one or more prominent nucleoli, increased mitotic activity, and phagocytosis.
 - Presence of immunoblasts may result in a mottled appearance to the affected site.
 - Immunoblasts may cluster or occasionally form sheets effacing portions of the tissue simulating a malignant lymphoma.
 - Immunoblasts may occasionally be binucleate, simulating the appearance of the Reed-Sternberg cells of Hodgkin lymphoma.
- Necrosis may be seen and is usually focally characterized by individual cell necrosis, although larger confluent zones of necrosis (geographic-type necrosis) may be present.
- A vascular proliferation with prominent endothelial cells is always present. In nodal involvement at least

some subcapsular sinuses are patent and contain a polymorphous lymphoid infiltrate similar to the interfollicular infiltrate.

- Atypical lymphoid proliferation may infiltrate:
 - Walls of the blood vessels
 - Outside the confines of the tonsil into adjacent soft tissues
- Histochemistry:
 - Histochemical stains for microorganisms are negative.
- Immunohistochemistry:
 - B-cell and T-cell reactivity:
 - Large cells show heterogeneous staining for CD20 and CD3.
 - Polytypical immunoglobulin staining of large cells
 - Immunoblasts may stain with CD30
 - Absence of CD15 immunoreactivity
 - Immunoreactivity can be seen for EBV latent membrane protein.
 - In situ hybridization for Epstein-Barr–encoded RNA (EBER) is positive in a proportion of cells including small and large cells.
- Cytogenetics and molecular genetics:
 - Clonal B cells are often absent; small clonal or oligoclonal B-cell populations may be found.
 - PCR analysis for detection of virus:
 - Determination of EBV viral load
 - Represents a more reliable and sensitive means for detecting the presence of virus than serodiagnosis

Differential Diagnosis

- Nonspecific reactive tonsillitis/lymphadenopathy
- Non-Hodgkin malignant lymphomas:
 - Especially of large cell or immunoblastic lymphoma (B-cell lineage) and anaplastic CD30+ large cell lymphoma
 - Markedly atypical interfollicular cellular proliferation in IM that may infiltrate blood vessels and/or outside the tonsil into adjacent soft tissues can easily be misinterpreted as a non-Hodgkin lymphoma
 - Attention to the clinical history, especially the relatively typical demographics associated with IM, should at least alert the pathologist to the possibility of this diagnosis.
 - Confirmatory laboratory analysis and absence of immunohistochemical and/or molecular biologic confirmation of a neoplastic process assist in avoiding the potential trap of misdiagnosing IM for a lymphoma.
- Hodgkin disease:
 - Primary Hodgkin lymphoma of the tonsils and/or mucosal sites of the upper aerodigestive tract

is exceedingly rare; when Hodgkin disease involves these sites, it usually does so secondarily following primary nodal disease.

- HIV-associated changes (see below)

Treatment and Prognosis

- Favorable clinical course often with resolution of symptoms over a period of several months
- Therapy is supportive, including rest and fluid intake.
- Rarely, serious and potentially fatal complications may develop and include airway obstruction and splenic rupture, the latter secondary to splenic involvement with massive splenomegaly.
- Most serious complications arise in individuals with X-linked lymphoproliferative disease (XLP):
 - XLP caused by mutations in *SH2D1A* and *XIAP* (*BIRC4*); may also occur in rare instances with no identified underlying genetic cause
 - Occurs in males with mutations in the signaling lymphocyte activation molecule-associated protein that regulates T and NK cells
 - Mutation mapped to chromosome Xq24-25 coding for cell surface receptor on T- and NK-cells but not B-cells
 - These patients are immunosuppressed and possess a rare, familial, fatal form of combined immunodeficiency.
 - Three most commonly recognized phenotypes of *SH2D1A*-related XLP are:
 - Hemophagocytic lymphohistiocytosis (HLH) associated with Epstein-Barr virus (EBV) infection:
 - Treatment similar to that of other life-threatening genetic hemophagocytic disorders and includes immunosuppressive agents such as steroids and etoposide; rituximab therapy may also be considered
 - Dysgammaglobulinemia:
 - Is typically hypogammaglobulinemia of one or more immunoglobulin subclasses
 - Treated by intravenous immunoglobulin (IVIG) therapy
 - Lymphoproliferative disorders (malignant lymphoma):
 - Malignant lymphomas are typically high-grade B-cell lymphomas, non-Hodgkin type, often extranodal, and in particular involving the intestine.
 - Treated with standard chemotherapy appropriate to the tumor
 - Regardless of clinical phenotype, the only curative treatment is allogeneic hematopoietic cell transplantation, which should be considered in most patients as early as possible.

Human Immunodeficiency Virus (HIV) Infection and Acquired Immunodeficiency Syndrome (AIDS)

- Clinical syndrome of acquired immune deficiency syndrome (AIDS) is characterized by opportunistic infection(s) and/or neoplasia with associated immunodeficiency.
- AIDS-related pathology may be seen in every organ system as a result of infection by the human immunodeficiency virus (HIV-1), the causative agent for AIDS.
- Head and neck represent a microcosm of the entire body with respect to the manifestations of AIDS.
- Virtually every conceivable pathologic process associated with HIV infection and AIDS can be found within the head and neck, including a wide variety of opportunistic infections, reactive lymphoproliferative processes, and hematolymphoid and non-lymphoid neoplasms:
 - These pathologic changes may be the initial manifestations of HIV infection or AIDS or they may represent a component of systemic disease.
- A variety of HIV- and AIDS-related pathologic lesions occur in the head and neck region ([Box 9-2](#)).

Pathogenesis

- Infection with HIV-1 initiates a series of events within the host immune system that ultimately leads to the destruction of cellular immunity, resulting in AIDS characterized by profound depletion of CD4⁺ lymphocytes rendering the host susceptible to the opportunistic infections and tumors that are the hallmark of AIDS.
- HIV-1 is:
 - A human retrovirus of the lentivirus genus
 - Membrane-bound, double-stranded RNA characterized by the presence of a unique enzyme, reverse transcriptase, at its core
 - Reverse transcriptase allows the viral RNA to be transcribed “backwards” into DNA and then inserted into the host genome
 - Major structural core proteins include:
 - p24 capsid protein
 - p18 matrix protein
- HIV-1 preferentially infects CD4⁺ (helper) T-cell lymphocytes and other cells of the immune system that bear the CD4 receptor and one of two chemokine receptors (CCR-5 and CXCR-4) on their surface:
 - These cells include CD4⁺ lymphocytes, dendritic cells, and macrophages.

BOX 9-2 HIV- and AIDS-Related Pathology of the Head and Neck**I. Opportunistic Infections***Viral*

- Cytomegalovirus
- Herpetic
- Others

Bacteria

- Mycobacteria (*Mycobacterium tuberculosis*, *Mycobacterium avium intracellulare*)
- Others

Fungal

- *Cryptococcus neoformans*
- Aspergillus
- Others

Protozoal

- *Toxoplasma gondii*
- *Pneumocystis jiroveci* (formerly *carinii*)
- Cryptosporidium
- Microsporidiosis

II. Benign Lesions

- Lymphadenopathy
- Extranodal lymphoid proliferation (adenotonsillar disease)
- HIV salivary gland disease
- Bacillary angiomatosis

III. Nonhematolymphoid Malignancies

- Kaposi sarcoma
- Malignant lymphomas
- Carcinomas
- Other

- Transmission of HIV-1 occurs through blood, sexual (body fluids), and maternofetal routes.
- HIV-2:
 - Following discovery of HIV-1, patients in West Africa with AIDS-like symptoms were identified whose serum antibodies reacted not with HIV-1 but with a distantly related lentivirus that was designated HIV-2.
 - HIV-2 is approximately 40% to 50% similar to HIV-1 in overall nucleotide sequence homology but with major differences in genomic organization, including an absence of the *vpu* gene present in HIV-1 and the addition of the *vpx* gene absent in HIV-1.
 - Antigenically HIV-2 and HIV-1 are distinct.
 - Like HIV-1, HIV-2 selectively infects CD4⁺ cells.
 - HIV-2 has the potential to cause profound immunodeficiency and an AIDS syndrome indistinguishable from that caused by HIV-1 but:
 - It appears to be less virulent than HIV-1.
 - It causes disease in a smaller fraction of individuals and over a more protracted period.

- Transmissibility of HIV-2 is less than that of HIV-1, and therefore the prevalence of HIV-2 is declining.

Epidemiology

- The overwhelming majority of early cases of HIV infection and AIDS in the United States and Europe were reported in men who have sex with men (homosexual and bisexual); although this remains the major risk group, intravenous drug users and women are the two groups with the highest increase in rates of AIDS in the United States:
 - Nearly 20% of new HIV infections are attributable to injecting drug use.
 - The main risk factor for women who acquire HIV during sex is the risk behavior of their male partners.
- Sub-Saharan Africa represents the epicenter of the global HIV/AIDS pandemic:
 - Most HIV transmissions in Africa (and Asia) are heterosexually transmitted.
 - Because infected females are usually at peak reproductive ages, the incidence of vertical transmission is also high.
- Recipients of contaminated blood and blood products (patients with hemophilia) were at much higher risk of acquiring the infection prior to the use of screening of blood products for HIV in 1984; this mode of transmission continues to be a threat in areas of the world where the blood supply is not screened.
- By January 2010 approximately 75 million people had become infected with HIV since the beginning of the epidemic in 1981; of those 75 million, more than 40 million people have died of AIDS.
- According to estimates by the Joint United Nations Program on HIV/AIDS:
 - 33.4 million people were living with HIV by December 2008.
 - 2.7 million people became newly infected in 2008, half of whom were young, between the ages of 15 and 24 years.
 - Continuing rise in the population living with HIV infection reflects a combination of continued high rates of HIV infection and beneficial impact of antiretroviral therapy (ART), resulting in fewer deaths.

Spectrum of Disease

- HIV-1 causes a spectrum of disease.
- With initial infection there are a constellation of findings that are caused directly by infection with HIV-1 and the patient's immune response.
- Transient, symptomatic illness is associated with high titer viremia and a vigorous response to the invading virus.

- In the United States, 40% to 90% percent of infected patients manifest this syndrome.
- Clinical manifestations of the primary infection are nonspecific:
 - A flu-like viral syndrome characterized by fever, fatigue, pharyngitis, lymphadenopathy including tonsillar and adenoidal enlargement, and a maculopapular rash
 - Due to the abundance of lymphoid tissue in the head and neck, including lymph nodes and extranodal lymphoid tissues (e.g., Waldeyer tonsillar ring and parotid gland), this anatomic region is especially likely to manifest these findings.
- During primary HIV infection there is a peak in viral load, which then decreases and levels out at what is known as the “set point”; this viral set point is prognostically significant:
 - Individuals with a low viral set point are more likely to progress slowly to AIDS (more than 10 years).
 - Individuals with a high viral set point are likely to progress rapidly to AIDS (less than 5 years).
- During primary infection the immune system responds vigorously to the virus:
- Patient is not immunodeficient.
- Patient is HIV-1 infected but does not have AIDS.
- As disease proceeds, especially if untreated, the virus begins to destroy the cellular arm of the patient’s immune system.
- As CD4⁺ cells of the immune system are destroyed, the patient loses the ability to fight off the myriad pathogens that are ubiquitous in our world.
- AIDS is the immunodeficiency that results from HIV-1 infection.
 - Infections seen in AIDS include pathogenic microorganisms as well as opportunistic infections.
- Diagnosis of HIV-1 infection is conceptually simple. Like most infections, it begins when the pathogen invades the host.
- Diagnosis of AIDS is much less clear cut:
 - AIDS is a diagnosis of criteria.
 - In the United States the diagnosis is made by fulfilling criteria developed by the CDC:
 - CDC classification system ([Table 9-1](#)) is based on three clinical categories (A, B, and C) and three CD4-T-cell count categories (1, 2, and 3).
 - HIV-1 viral load, which has become a critical tool in diagnosing and managing patients with HIV-1 infection, is not included in the CDC criteria.
- Early diagnosis is critical, owing to effective initiation of antiretroviral therapy that may, if administered in the earliest phase of infection, have a major positive impact on prognosis and long-term survival.
- Indicators of HIV disease and AIDS are listed in [Box 9-3](#):
 - Clinical staging and case definition of HIV for resource-constrained settings were developed by WHO in 1990 and revised in 2007.

TABLE 9-1 Clinical Categories: CDC Classification System for HIV-Infected Adults or Adolescents

CD4 ⁺ T-Cell Categories	A Asymptomatic, Acute, or PGL	B* Symptomatic, B-Conditions	C AIDS-Indicator Conditions
1 = ≥500/ml or 29%	A1	B1	C1
2 = 200-499/ml or 14% to 28%	A2	B2	C2
3 = <200/ml or immunologic AIDS	A3	B3	C3

PGL, Progressive generalized lymphadenopathy.

Persons under subcategories A3, B3, C1, C2, and C3 are reportable as AIDS cases in the United States and territories (effective 01 January 1993).

*Category symptomatic conditions are defined as symptomatic conditions occurring in an HIV-infected adolescent or adult that meets at least one of the following criteria:

They are attributed to HIV infection or indicate a defect in cell-mediated immunity.

They are considered to have a clinical course or management that is complicated by HIV infection.

Examples include, but are not limited to, the following:

Bacillary angiomatosis
 Oropharyngeal candidiasis (thrush)
 Vulvovaginal candidiasis, persistent or resistant
 Pelvic inflammatory disease (PID)
 Cervical dysplasia (moderate or severe)/cervical carcinoma in situ
 Hairy leukoplakia, oral
 Herpes zoster (shingles), involving two or more episodes or at least one dermatome
 Idiopathic thrombocytopenic purpura
 Constitutional symptoms, such as fever (>38.5°C) or diarrhea lasting >1 month
 Peripheral neuropathy

BOX 9-3 Indicators of HIV Disease and AIDS**Clinical Stage 1**

- Asymptomatic HIV infection
- Persistent generalized lymphadenopathy
- Acute (primary) HIV infection with accompanying illness or history of acute HIV infection

Clinical Stage 2

- Moderate unexplained weight loss (<10% of presumed or measured body weight)
- Recurrent respiratory infections (sinusitis, tonsillitis, otitis media, and pharyngitis)
- Herpes zoster
- Angular cheilitis
- Recurrent oral ulceration
- Papular pruritic eruptions
- Seborrheic dermatitis
- Fungal nail infections

Clinical Stage 3

- Unexplained severe weight loss (>10% of presumed or measured body weight)
- Unexplained chronic diarrhea for >1 month
- Unexplained persistent fever for >1 month (>37.6°C, intermittent or constant)
- Persistent oral candidiasis (thrush)
- Oral hairy leukoplakia
- Pulmonary tuberculosis (current)
- Severe presumed bacterial infections (e.g., pneumonia, empyema, pyomyositis, bone or joint infection, meningitis, bacteremia)
- Acute necrotizing ulcerative stomatitis, gingivitis, or periodontitis
- Unexplained anemia (hemoglobin <8 g/dl)
- Neutropenia (neutrophils <500 cells/ μ l)
- Chronic thrombocytopenia (platelets <50,000 cells/ μ l)

Clinical Stage 4

- HIV wasting syndrome, as defined by the CDC (see [Table 9-1](#))
- *Pneumocystis* pneumonia
- Recurrent, severe bacterial pneumonia
- Chronic herpes simplex infection (orolabial, genital, or anorectal site for >1 month or visceral herpes at any site)
- Esophageal candidiasis (or candidiasis of trachea, bronchi, or lungs)
- Extrapulmonary tuberculosis
- Kaposi sarcoma
- Cytomegalovirus infection (retinitis or infection of other organs)
- Central nervous system toxoplasmosis
- HIV encephalopathy
- Cryptococcosis, extrapulmonary (including meningitis)
- Disseminated nontuberculosis mycobacteria infection
- Progressive multifocal leukoencephalopathy
- Candida of the trachea, bronchi, or lungs
- Chronic cryptosporidiosis (with diarrhea)
- Chronic isosporiasis
- Disseminated mycosis (e.g., histoplasmosis, coccidioidomycosis, penicilliosis)
- Recurrent nontyphoidal *Salmonella* bacteremia
- Lymphoma (cerebral or B-cell non-Hodgkin)
- Invasive cervical carcinoma
- Atypical disseminated leishmaniasis
- Symptomatic HIV-associated nephropathy
- Symptomatic HIV-associated cardiomyopathy
- Reactivation of American trypanosomiasis (meningoencephalitis or myocarditis)

- Staging is based on clinical findings that guide the diagnosis, evaluation, and management of HIV/AIDS, and it does not require a CD4 cell count.
- The staging system is used in many countries to determine eligibility for antiretroviral therapy, particularly in settings in which CD4 testing is not available.
- Clinical stages are categorized as 1 through 4, progressing from primary HIV infection to advanced HIV/AIDS (see [Box 9-3](#)).
- These stages are defined by specific clinical conditions or symptoms.
- For the purpose of the WHO staging system, adolescents and adults are defined as individuals aged 15 years or older.
- The WHO Case Definition for HIV Infection and AIDS is listed in [Box 9-4](#).
 - Cases diagnosed with advanced HIV infection (including AIDS) not previously reported should be reported according to a standard case definition.

BOX 9-4 WHO Case Definition for HIV Infection**Adults and Children 18 Months or Older**

- HIV infection is diagnosed based on:
 - Positive HIV antibody testing (rapid or laboratory-based enzyme immunoassay). This is confirmed by a second HIV antibody test (rapid or laboratory-based enzyme immunoassay) relying on different antigens or on different operating characteristics.
- and/or
 - Positive virologic test for HIV or its components (HIV-RNA or HIV-DNA or ultrasensitive HIV p24 antigen) confirmed by a second virologic test obtained from a separate determination

Children Younger Than 18 months

- HIV infection is diagnosed based on:
 - Positive virologic test for HIV or its components (HIV-RNA or HIV-DNA or ultrasensitive HIV p24 antigen) confirmed by a second virologic test obtained from a separate determination taken more than 4 weeks after birth
 - Positive HIV antibody testing is not recommended for definitive or confirmatory diagnosis of HIV infection in children until 18 months of age.

BOX 9-5 Criteria for Diagnosis of Advanced HIV (Including AIDS*)

- Clinical criteria for diagnosis of advanced HIV in adults and children with confirmed HIV infection:
 - Presumptive or definitive diagnosis of any stage 3 or stage 4 condition[†] and/or
- Immunologic criteria for diagnosing advanced HIV in adults and children 5 years or older with confirmed HIV infection:
 - CD4 count less than 350 per mm³ of blood in an HIV-infected adult or child and/or
- Immunologic criteria for diagnosing advanced HIV in a child younger than 5 years of age with confirmed HIV infection:
 - %CD4⁺ <30 among those younger than 12 months
 - %CD4⁺ <25 among those aged 12 to 35 months
 - %CD4⁺ <20 among those aged 36 to 59 months

*AIDS in adults and children is defined as: clinical diagnosis (presumptive or definitive) of any stage 4 condition (defined in Annex 1) with confirmed HIV infection: OR immunologic diagnosis in adults and children with confirmed HIV infection and >5 years of age; first-ever documented CD4 count less than 200 per mm³ or %CD4⁺ <15: OR among children with confirmed HIV infection aged 12 to 35 months first ever documented %CD4 <20: OR among children with confirmed HIV infection and less than 12 months of age first ever documented %CD4 <25.

[†]Annex 1 provides criteria for presumptive or definitive diagnosis of all conditions.

- Advanced HIV infection is diagnosed based on clinical and/or immunologic (CD4) criteria among people with confirmed HIV infection (Box 9-5).
- AIDS case reporting for surveillance is no longer required if HIV infection or advanced HIV infection is reported.

HIV Infection of Extranodal Lymphoid Tissues of Waldeyer Tonsillar Ring (Figs. 9-10 and 9-11)

Definition: Primary HIV infection of the extranodal tissues of Waldeyer ring occurring in association with known systemic disease or representing the initial manifestation of HIV infection in otherwise asymptomatic patients not known to be HIV infected.

Clinical

- More common in men than women, and occurs most frequently in the third to fifth decades of life (median age, fourth decade):
 - May occur in pediatric ages
- HIV infection may first present clinically as enlargement of the lymphoid tissues of Waldeyer's ring, including the tonsils and adenoids.
- Clinical presentations vary and include nasal congestion, airway obstruction, sore throat (pharyngitis),

otitis media unresponsive to antibiotic therapy, otalgia, facial weakness, fever, and a nasopharyngeal or tonsillar mass.

- Clinical spectrum of HIV infection includes three phases: early or acute, chronic, and crisis or final.
- Morphologic changes parallel the course of HIV infection (see below).
- In early stages of disease:
 - Florid follicular hyperplasia of lymphoid tissues results in enlargement of the affected sites, causing lymphadenopathy as well as enlargement of the tonsils and/or adenoids.
 - Tonsillar enlargement may cause airway obstruction and/or otitis media and raise the clinical concern for neoplastic involvement of these sites.
 - Similar to the lymphoid tissue changes that occur with the progression of disease, the identification of the HIV also changes over time:
 - In nodal tissues, the follicular dendritic cells of the germinal centers have been shown to be reservoirs of HIV RNA.
 - Follicular dendritic cells entrap but do not actively produce HIV, allowing for presentation of the virus to competent immune cells of B-cell lineage.
 - With progression of disease and continued immune suppression, the germinal centers involute and then disappear.
- Clinically, the tonsils and adenoids are enlarged, usually bilaterally, but unilateral enlargement may occur:
 - Enlargement of the tonsils or adenoids may raise the concern of a hematolymphoid or epithelial neoplasm prompting surgical removal of the enlarged organ.
- Concurrent (unilateral) cervical adenopathy may be present.
- Large ulcers leading to complete destruction of the tonsil may also be present.
- Patients may or may not be known to be infected with HIV and/or suffering from AIDS:
 - Risk factors for the patients who were known or suspected to be HIV positive include men who have sex with men (homosexual and bisexual), blood transfusion recipients, and/or intravenous drug abuse.
 - Patients not known to be HIV infected often present without any of the clinical stigmata of HIV infection.
- Serologic evaluation is confirmatory for HIV infection.

Pathology

Histology

- Histomorphologic changes seen in affected lymph nodes and peripheral lymphoid tissues represent a

Fig. 9-10. Human immunodeficiency virus (HIV) infection of Waldeyer's tonsillar tissues.

A, Early histologic manifestations of HIV infection include the presence of florid follicular hyperplasia (FFH) characterized by enlarged and irregularly shaped germinal centers with loss or attenuation of mantle lymphocytes; some germinal centers approximate the surface epithelium. **B**, Three lymphoid follicles in varying stages, including the two larger ones showing attenuated to partially absent mantle cell lymphocytes, and the smaller germinal center (*center*) infiltrated by small lymphocytes referred to as follicle lysis resulting in creating a "moth-eaten" appearance. **C**, Higher magnification shows (*left*) follicular hyperplasia with absent mantle cell lymphocytes and (*right*) follicle lysis characterized by "infiltrating" small lymphocytes and absence of clearly defined mantle zones. **D**, Multinucleated giant cells are characteristically localized near or within the surface epithelium and/or near or within crypt epithelium (*not shown*). **E**, Histologic features in patients with more advanced stages of disease include the effacement of lymphoid tissue architecture, loss of the normal lymphoid cell population with replacement by a benign plasma cell infiltrate, and the presence of increased vascularity.

Fig. 9-11. Immunohistochemistry and in situ hybridization (ISH) in HIV infection.

Confirmation of HIV infection by immunohistochemical reactivity with HIV p24 core antigen. **A**, (left) HIV-infected tonsillar tissue showing follicle lysis; (right) HIV p24 immunoreactivity within follicular dendritic cells. **B**, (left) HIV-infected tonsillar tissue showing multinucleated giant cells that are (right) HIV p24 immunoreactive. **C**, In situ hybridization for HIV-1 RNA using antisense riboprobe, darkfield microscopy, showing signal in enlarged and irregularly shaped germinal centers, as well as in scattered interfollicular cells and multinucleated giant cells, the latter approximating the epithelial layer.

continuum that varies according to the duration and progression of disease.

- Histomorphologic changes in HIV-induced tonsillar and adenoidal enlargement vary with the progression of disease.

Acute and/or Chronic Stage

- May include florid follicular hyperplasia with and without follicular fragmentation, and follicle lysis with areas of follicular involution
- Additional findings included the presence of monocytoïd B-cell hyperplasia, paracortical and interfollicular zone expansion with immunoblasts and plasma cells, interfollicular clusters of high endothelial venules, intrafollicular hemorrhage, and the presence of multinucleated giant cells (MGC).
- MGC characteristically cluster adjacent to or within the adenoidal surface epithelium or the tonsillar crypt epithelium.

Advanced Stage

- Features correlate with the lymphoid obliteration seen in the terminal stages of HIV infection or AIDS:
- Effacement of nodal architecture, loss of the normal lymphoid cell population with replacement by a benign plasma cell infiltrate, and the presence of increased vascularity.
- MGC characteristically seen in the early and chronic stages of disease are not identified in the more advanced stages of HIV infection.
- Histochemistry:
 - Special stains for microorganisms (other than HIV) are negative.
- Immunohistochemistry:
 - Reactivity for the HIV core antigen p24 (gag protein), an indicator of active HIV infection consistently identified in the early and chronic stages of disease:
 - Anti-HIV p24 reactivity is seen within the follicular dendritic cell (FDC) network of the germinal centers, in scattered interfollicular lymphocytes, in the multinucleated giant cells, and within intraepithelial cells of crypt epithelium.
 - HIV p24-positive intraepithelial cells are S100 protein (a dendritic cell marker) positive, and their morphologic appearance correlates with the appearance of dendritic cells (DC).
 - Reactivity with B-cell (CD20) and T-cell markers or subsets (CD45RO, CD3, OPD4) is seen within the germinal centers and in the interfollicular regions, as well as in scattered intraepithelial cells.

- In more advanced stages of disease, characterized by loss of germinal centers and the presence of a predominant plasma cell infiltrate:
 - Show a relative absence of lymphoid cell markers (CD20, CD3, or OPD4)
 - Plasma cell infiltrate shows reactivity with kappa and lambda light chains indicative of a benign proliferation.
- Surface and crypt epithelia are cytokeratin reactive.
- Immunoreactivity with Epstein-Barr virus–latent membrane protein (EBV-LMP), herpes simplex virus (HSV), or cytomegalovirus (CMV) is not present
- Cytogenetics and molecular genetics:
 - Evidence of HIV RNA by in situ hybridization is seen in the follicular dendritic cell network, in the multinucleated giant cells, and in mature lymphocytes localized to the germinal centers, interfollicular zones, and within the surface and/or crypt epithelia.
 - Strongest signal is present in the multinucleated giant cells.

Differential Diagnosis

- Other infectious diseases
- Infectious-related proliferative processes (e.g., infectious mononucleosis)
- Malignant lymphoma

Treatment and Prognosis

- Early initiation of antiretroviral therapy has reduced HIV-associated morbidity and has significantly prolonged life and disease-free interval.
- Antiretroviral therapy can reliably reduce viral loads to levels below 50 copies/ml when circulating virus is susceptible to available drugs:
 - When viral loads are reduced to low levels, further immune decline is usually prevented and immune function is usually improved.
 - Most patients with effective virologic suppression demonstrate improvement in CD4 count but a few patients will not show benefit for unknown reasons.
- As HIV infection of Waldeyer tonsillar ring may be the initial manifestation of HIV infection, recognition of its pathologic features is essential to initiation of antiretroviral therapy.

AIDS-Related Opportunistic Infectious Diseases of the Pharynx

- A number of opportunistic infections occurring in association with the immune-compromised state

caused by HIV or secondary to AIDS can be found to infect the upper aerodigestive tract, including viruses, fungi, and protozoa.

Viruses

- Infestation of head and neck sites in HIV-positive and AIDS patients is common.
- Among the more common viruses that infect head and neck sites in this setting are cytomegalovirus and herpesvirus (simplex and zoster).

Cytomegalovirus (CMV) (Fig. 9-12)

- CMV is a large, double-stranded DNA virus and a member of the herpesvirus family.
- In fully immunocompetent individuals, CMV rarely causes clinically evident disease.
- When immune mechanisms are deficient, especially those mediated by CD4 positive and CD8 positive lymphocytes, latent virus replicates and causes pathologic injury.
- CMV is the most common opportunistic pathogen recognized at autopsy in AIDS patients.
- In general, CMV infection involving the head and neck is not common; when it occurs in the head and neck, CMV infection is seen as an ulcerative mucocutaneous lesion.

Pathology

Gross

- Single or multiple, oval, tan-white, ulcerated lesions with a hyperemic rim with or without associated exudates

Histology

- Mucosal ulceration, necrosis, and cytopathic effects
- Cytopathic findings include:
 - Nucleomegaly
 - Characteristic intranuclear and/or intracytoplasmic inclusions typically in nonepithelial cells, including endothelial cells and fibroblasts rather than in squamous cells:
 - Intranuclear basophilic Cowdry type B inclusion (so-called owl's eye inclusions)
 - Ill-defined amphophilic cytoplasmic inclusions
- Immunohistochemistry:
 - Positive CMV immunoreactivity and/or in situ hybridization

Treatment

- Antiviral therapy (valganciclovir and ganciclovir) may prove effective.
- In AIDS patients, CMV infection generally resolves when CD4 counts exceed 100/mm³ but is a grave prognostic sign if counts do not recover to those levels.

Fig. 9-12. Cytomegalovirus (CMV) pharyngitis.

A, Multiple, discrete, oval mucosal lesions are seen. **B**, Histologic findings include the presence of mesenchymal cells showing cytomegaly with characteristic intranuclear and intracytoplasmic inclusions (top of image). **C**, In situ hybridization for CMV confirms the diagnosis showing intranuclear and intracytoplasmic positivity.

Herpes Simplex Virus (HSV) (Figs. 9-13 and 9-14)

- Herpes simplex viruses are large, enveloped, double-stranded DNA viruses and members of the family Herpesviridae.
- Two distinct subtypes of herpes simplex virus are identified:
 - Type 1 referred to as the “oral” type
 - Type 2 referred to as the “genital” type:
 - Virus type is not necessarily a reliable indicator of anatomic site affected, especially with changing sexual habits.
 - Distinction between HSV-1 and HSV-2 not relevant
- Because of its tendency to infect cells of ectodermal origin (skin or mucous membranes) herpes simplex virus (HSV) is a frequent cause of mucocutaneous disease in the HIV-positive patient.
- Head and neck manifestations are those of an ulcerated lesion with involvement of intraoral, nasal cavity, lip, external ear, pharynx, and tonsil; in addition, enlargement and tenderness of cervical and submental lymph nodes may be seen.
- Infection of the pharynx may appear as vesicular lesions that bleed easily and may be covered with a black crust or as shallow tonsillar ulcers covered with gray exudates.
- Herpes zoster may occur as varicella (chickenpox) or as dermatomal zoster (shingles); the latter, while not specific for HIV infection, appears to be related to HIV infection and may represent an early marker for the immunosuppression associated with HIV infection.
- Herpes zoster can localize to any dermatome, is neurotropic, and can cause unremitting pain.
- Head and neck manifestations include involvement of the eighth nerve or geniculate ganglion (Ramsay Hunt syndrome), producing severe ear pain, hearing loss, vertigo, and facial nerve paralysis.

Pathology

Gross

- Single or multiple, oval, tan-white, ulcerated lesions with a hyperemic rim with or without associated exudates

Histology

- In mucosal sites, there is focal ulceration, intraepithelial vesicles, acantholysis, neutrophilic infiltrate, necrosis, balloon degeneration of epithelial cells, and intranuclear inclusions within the degenerating epithelial cells:
 - Diagnostic cytopathic features include nuclear molding, multinucleated giant cells, and eosinophilic inclusions.

Fig. 9-13. Herpes simplex virus infection.

Mucocutaneous herpes simplex virus infection with involvement of the (A) external lip and (B) labial mucous membrane (herpetic stomatitis). C, Herpes zoster infection or dermatologic zoster (shingles).

Fig. 9-14. Herpes simplex virus infection.

A, Histologic findings in herpes simplex virus (HSV) includes balloon degeneration of epithelial cells with intranuclear inclusions within degenerating epithelial cells (arrows). B, In situ hybridization for HSV confirms the diagnosis showing intranuclear positivity.

- The edge of the ulcer and sloughed squamous cells are the best sites for identification of characteristic cytopathic changes.
- Herpes zoster virus:
 - Intranuclear inclusions indistinguishable from those seen in herpes simplex are identified.
- Immunohistochemistry:
 - Positive HSV immunoreactivity and/or in situ hybridization
- DNA amplification by PCR has significantly improved sensitivity for confirmation of HSV.

Treatment

- Acyclovir antiviral chemotherapy is the first-line treatment for the management of herpes simplex virus 1 (HSV-1) and 2 (HSV-2) diseases.

Fig. 9-15. Measles tonsillitis.

Reactive follicular epithelial hyperplasia with interfollicular multinucleated (Warthin-Finkeldey type) giant cells.

Other Viruses

- Other viral diseases of the pharynx (i.e., tonsils) in immune-competent individuals includes measles (Fig. 9-15):
 - Acute childhood illness caused by RNA paramyxovirus
 - Also referred to as rubeola
 - Highly contagious and transmitted by oral and respiratory secretions
 - Patients are typically immunocompetent.
 - Availability of live measles virus vaccine has made this disease less common in the United States.
 - Following a prodromal period, a generalized rash develops beginning on the face and spreading to the trunk and extremities:
 - Rash usually resolves within 10 days.
 - Immunosuppressed patients may not develop characteristic rash.
 - Tonsillar involvement results in reactive follicular hyperplasia with interfollicular Warthin-Finkeldey-type giant cells characterized by multiple nuclei arranged in grape-like clusters.

FUNGI

- See Section 2, Oral Cavity, for more complete discussion.
- Many fungi including *Candida* species may secondarily infect HIV-positive patients and are implicated in causing disease in the HIV-infected patient.
- In the head and neck the single most important fungal pathogen is the *Candida* species.
- Oral candidiasis (thrush) frequently occurs in AIDS patients, and its presence is a strong indication for the subsequent development of AIDS.
- Identification of the microorganism can be accomplished by culture on Sabouraud agar.
- *Candida* is seen in association with oral hairy leukoplakia, where it is identified on the surface of the lesion; this form of *Candida* infection is unrelated to AIDS.
- Candidiasis limited to the oral cavity and/or pharynx is treated with topical nystatin or oral ketoconazole and its derivatives; however, if oral or pharyngeal infection represents part of systemic involvement, amphotericin B is the preferred drug.

- Oropharyngeal histoplasmosis is closely associated with immunosuppression status, especially in patients presenting AIDS, and oropharyngeal histoplasmosis may represent the initial manifestation of disseminated histoplasmosis.

BACTERIA AND SPIROCHETES

- AIDS patients may experience an increased incidence of otolaryngic gonorrhea and syphilis.

Gonorrhea

Definition: Localized and systemic disease caused by *Neisseria gonorrhoeae*, a pyogenic gram-negative diplococcus.

Clinical

- Otolaryngologic manifestations include gonococcal pharyngitis, which generally is asymptomatic but may present with sore throat, tonsillar hypertrophy, or cervical adenopathy.
- Microorganism infects mucosal and glandular structures.

Pathology

Histology

- Acute inflammation may be present but is not common
- Intracellular diplococci may be seen by methylene blue or Brown and Brenn staining within the submucosa (intracellularly in leukocytes) and occasionally in cellular debris in tonsillar crypts.
- Gram stain smears from the pharynx are unreliable due to the presence of other organisms, so samples must be cultured on appropriate media (chocolate agar) for identification.

Treatment and Prognosis

- Ceftriaxone is the preferred drug for routine treatment of gonorrhea.
- Recommendation includes to treat all patients with gonorrhea with an oral regimen active against *C. trachomatis*, usually azithromycin:
 - Dual therapy may enhance efficacy of treatment for pharyngeal gonorrhea and using more than one drug may retard selection of antimicrobial resistance in *N. gonorrhoeae*.
 - Such treatment is warranted, even in persons who test negative for *C. trachomatis*.

Syphilis (Fig. 9-16)

Definition: Systemic venereal disease caused by *Treponema pallidum*, a member of the family Spirochaeta-

ceae, which includes *T. pertenue* (yaws) and *T. carateum* (pinta).

Clinical

- Clinical stages of syphilis are primary, secondary, tertiary, and congenital, any of which can affect virtually every site in the head and neck, causing an array of clinical manifestations.
- Protean clinical manifestations include involvement of the head and neck resulting in:
 - Tonsillar involvement manifesting as a painless solitary chancre, which appears at the site of inoculation in the primary stage:
 - Chancres may clinically mimic a neoplasm.
 - Skin lesions and lymphadenopathy (seen in 90% of the patients in the secondary or disseminated stage):
 - Characteristic chancre develops at the site of infection.
 - Oral involvement may include the lips, tongue, palate, gingiva, and tonsils.
 - Pharyngotonsillitis may be a presenting symptom in secondary syphilis, and mucosal involvement produces so-called mucous patches, which are highly contagious.
- Other head and neck symptoms in the secondary stage may include rhinitis, laryngitis, pharyngitis, cranial nerve deficits, sensorineural deafness, labyrinthitis, and glossitis.
- Tertiary stage typically involves the central nervous system (neurosyphilis) and aorta (cardiovascular syphilis); however, localized, nonprogressive lesions may develop in mucosal otolaryngologic sites termed benign tertiary syphilis or gummas:
 - Gummatous reaction represents a pronounced immunologic reaction of the host.
- Laboratory evaluation includes two types of serologic tests for syphilis:
 - Nontreponemal (nonspecific) antibody tests:
 - Detect antibodies to lipoprotein material and cardiolipin released from cells damaged by treponemes
 - Screen for disease and monitor course of disease
 - Include venereal disease research laboratory test (VDRL), rapid plasma reagin (RPR), unheated serum reagin (USR), and toluidine red unheated serum (TRUST)
 - Treponemal (specific) antibody tests:
 - Detect the presence of antibodies to treponemal antigens and used to confirm positive nontreponemal screening test or to confirm infection in face of negative nontreponemal test in late or latent disease stages, which can occur in up to 30% of patients with tertiary syphilis
 - Include fluorescent treponemal antibody absorption test (FTA-ABS)

Fig. 9-16. Syphilis.

A, Chancre of the lip. **B**, Syphilitic pharyngotonsillitis appearing as diffuse white exudate overlying the soft palate, uvula, and tonsils. **C**, Histologic findings include an inflammatory infiltrate predominantly composed of plasma cells, as well as scattered histiocytes, lymphocytes, and neutrophils with a tendency to cluster around small blood vessels. **D**, Microorganisms can be demonstrated by Warthin-Starry staining appearing as elongated, thin rod-like, or corkscrew-shaped structures. **E**, Hutchinson's incisors seen in congenital syphilis in which the teeth are small with abnormal notching.

- Microhemagglutination–T. *palladium* test (MHA-TP):
 - MHA-TP is preferred owing to its relative simplicity.
- Enzyme immunoassay (EIA) increasingly used for screening

Pathology

Histology

- An inflammatory infiltrate can be seen that is predominantly composed of plasma cells with scattered histiocytes, lymphocytes, and polymorphonuclear leukocytes:
 - Inflammatory infiltrate has a tendency to involve small blood vessels that display endothelial cell proliferation (“plasma cell endarteritis”).
 - Concentric layers are produced that markedly narrow affected vessel’s lumen, resulting in obliterative endarteritis.
 - Obliterative endarteritis coupled with the inflammatory infiltrate produced by the spirochetes represents the histologic hallmarks of the disease.
- Histochemistry:
 - Microorganisms can be demonstrated in the chancre by Warthin-Starry staining and appear as elongated, thin, rod-like structures.
- Diagnosis of treponematoses:
 - Darkfield microscopy
 - Fluorescence microscopy
 - Immunohistochemistry

Differential Diagnosis

- Nonspecific inflammatory reactions

Treatment and Prognosis

- Treatment of choice remains penicillin:
 - Penicillin G and other β -lactam antibiotics:
 - Single intramuscular injection
 - For those persons allergic to penicillin, doxycycline and tetracycline are effective alternatives.

Additional Notes

- Congenital syphilis:
 - Develops via transplacental infection
 - Primarily occurs with mucocutaneous and osseous manifestations including in decreasing percentage: frontal boss > short maxilla > high palatal arch > saddle nose > mulberry molars > Hutchinson incisors > sternoclavicular thickening > interstitial keratitis > rhagades > VIII nerve deafness

Bacillary Angiomatosis (BA) (Fig. 9-17)

Definition: Pseudoneoplastic capillary proliferative lesion almost exclusively occurring in immunocompro-

mised patients (as a complication of HIV infection), usually presents as a cutaneous vascular lesion and is caused by an opportunistic bacterial infection belonging to *Bartonella* species (formerly *Rochalimaea*).

Synonyms: Epithelioid angiomatosis; epithelioid hemangioma-like vascular proliferation

Pathogenesis

- *Bartonella* is a genus of small gram-negative bacilli that includes a number of species pathogenic for humans, including:
 - *Bartonella henselae*
 - *Bartonella quintana*
 - *Bartonella bacilliformis*
 - *Bartonella elizabethae*
- Bacillary angiomatosis is caused by *B. henselae* or *B. quintana*.

Clinical

- No gender predilection; occurs over a wide age range
- Most commonly presents as a cutaneous lesion commonly associated with systemic symptoms, including fever, chills, weight loss, and night sweats
- Clinically, lesions are similar in appearance to lobular capillary hemangioma (pyogenic granuloma) and Kaposi sarcoma characterized by the presence of multiple erythematous papules with or without crusting.
- May involve other organs sites, including:
 - Lymph nodes
 - Spleen and liver
 - Mucosal sites of the upper respiratory tract
 - Conjunctiva
- May occur in association with Kaposi sarcoma
- May occur in immune-competent individuals

Pathology

Gross

- Varies widely from cutaneous erythematous papules to mushroom-shaped papules and nodules to deep-seated rounded lesions without change in skin color
- Exceptionally, may appear as a mucosal-based, erythematous nodular proliferation

Histology

- Regardless of its clinical presentation, the histologic features are the same and include a well-circumscribed lobular capillary proliferation with overall features similar to those seen in lobular capillary hemangioma.
- Small capillaries are arranged around ectatic vessels, which are lined by prominent-appearing endothelial cells.
- Cytologic atypia, mitotic figures, and necrosis are not usually present but occasionally may be seen.

Fig. 9-17. Bacillary angiomatosis (BA).

A, Lymph node replaced by well-circumscribed lobular proliferation. **B**, Proliferation of small capillaries lined by prominent-appearing endothelial cells; an associated fibrotic stroma is present. **C** and **D**, Solid area obscuring the vascular proliferation including atypical, enlarged vesicular nuclei with prominent nucleoli; note the presence of neutrophils and/or neutrophilic debris representing an important histologic feature in BA. **E**, Warthin-Starry staining shows slender-appearing rod-shaped bacilli representing *Bartonella* species (formerly *Rochalimaea*), either *B. henselae* or *B. quintana*. Bacilli form the darker staining clumps.

- Solid areas may be present and may obscure the vascular proliferation.
- A variable edematous, mucinous, or fibrotic stroma is seen separating the lobular proliferation.
- An important histologic feature is the presence of neutrophils and neutrophilic debris adjacent to the capillary proliferation; associated with the neutrophils are granular clumps.
- Typically lacks spindled cells, interconnecting vascular channels, or hyaline globules.
- Overlying epithelium may be ulcerated, thinned, or show pseudoepitheliomatous hyperplasia.
- Histochemical stains:
 - Warthin-Starry staining shows individual slender rod-shaped bacilli, which form the darker staining granular clumps.
- Immunohistochemistry:
 - Endothelial cells are positive for CD31, CD34, Factor VIII-related antigen
 - HHV-8 negative
- PCR used to identify the presence of microorganisms confirming the diagnosis:
 - Routine cultures considered inadequate for isolating bacilli.

Differential Diagnosis

- Lobular capillary hemangioma
- Epithelioid hemangioma
- Angiosarcoma
- Kaposi sarcoma:
 - HHV-8 positive

NOTE: The presence of granular material, neutrophils, and neutrophilic debris and the absence of cytologic atypia, ramifying and interconnecting vascular channels, necrosis, mitotic activity, and hyaline globules, assist in differentiating BA from these other vascular lesions.

- Verruga peruana, another vascular proliferation process caused by an infectious agent (*Bartonella bacilliformis*), is endemic to Peru:
 - Presence of characteristic inclusions referred to as Rocha-Lima inclusions allows for differentiation
 - Rocha-Lima inclusions that consist of conglomerates of intracytoplasmic granules that are colored red by Romanowsky-Giemsa stains may be seen within the endothelial cells.
 - Finding of Rocha-Lima inclusions on light-microscopic studies and/or the demonstration of *Bartonella* organisms in the lesions can establish the diagnosis in a given lesion.

Treatment and Prognosis

- Treatment for BA is directed at the causative microorganism:
 - Erythromycin is the preferred drug and is effective, often resulting in the resolution of the lesions.

Fig. 9-18. *Pneumocystis jiroveci* (formerly *carinii*).

Left, foamy exudate within which the (right) characteristic microorganisms are identified by Gomori methenamine silver (GMS) stain.

- Tetracyclines are the first alternative in patients who cannot tolerate erythromycin.
- Combination of doxycycline plus rifampin may be used in immunocompromised patients with severe disease
- If left untreated, BA is progressive and potentially life threatening.

PROTOZOA (Fig. 9-18)

- *Pneumocystis jiroveci* (formerly *carinii*) is an opportunistic organism that is usually associated with pneumonia in the immunodeficient host and is the most common life-threatening infection in AIDS patients.
- Unusual for pneumocystis to cause clinical manifestations outside of the pulmonary system
- In the head and neck, pneumocystis infection has been identified involving the external auditory canal and the middle ear (see Section 7).
- Clinical manifestations differ according to the site of infection and include ear pain, hypomobility of the tympanic membrane, and otitis media, as well as conductive and sensorineural hearing losses.
- Presumed mode of dissemination from the lung to extrapulmonary sites is via vascular channels; typically, the pulmonary manifestations of pneumocystis infection precede those of extrapulmonary involvement; however, on occasion the initial diagnosis of AIDS has been made following identification of its associated pathology in extrapulmonary locations.

Pathology

Gross

- May appear as a polypoid mass arising from the external or middle ear

Histology

- Findings are similar to those seen in the lung and include a submucosal foamy exudate within which the organism can be identified by Gomori methenamine silver (GMS) stain.
- Overlying epithelium is often ulcerated.

Treatment

- Treatment of otologic pneumocystosis should be directed at systemic pneumocystosis even in the face of subclinical pulmonary manifestations.

TANGIER DISEASE (Fig. 9-19)

Definition: Severe high-density lipoprotein (HDL) deficiency syndrome characterized by the accumulation of cholesterol in tissue macrophages (xanthomatous cells) in various body sites and prevalent atherosclerosis.

Clinical

- Initially observed on Tangier Island in the Chesapeake Bay area of the United States
- Rare autosomal-recessive disorder caused by mutation in the ATP binding cassette transporter 1 (*ABCA1*) gene:
 - *ABCA1* gene mediates the secretion of excess cholesterol from cells into the HDL metabolic pathway.
 - HDLs play a central role in transporting cholesterol from peripheral tissues to the liver for elimination from the body.
 - Impairment of HDL-mediated cholesterol transport favors cholesterol deposition in the

arterial wall and promotes development of arteriosclerosis.

- No gender predilection; occurs in all age groups
- Clinical manifestations relate to deposition of cholesteryl esters in nonadipose tissues chiefly in:
 - Peripheral nerves leading to neuropathy
 - Reticulo-endothelial organs, such as tonsils, liver, spleen, lymph nodes, and the cornea, causing their enlargement and discoloration
- Tonsillar involvement results in symptoms of pharyngotonsillitis.
- An association with early cardiovascular disease can be variable.
- A unique phenotype of Tangier disease from a novel splice site mutation in the *ABCA1* gene has been reported that is associated with a central nervous system presentation resembling multiple sclerosis and the presence of premature atherosclerosis.
- Laboratory findings:
 - Deficiency of HDLs, low levels of apoproteins, low levels of high-density lipoprotein cholesterol (HDL-C), low to normal low-density lipoprotein levels, and normal to increased plasma triglyceride levels

Pathology

Gross

- Tonsils are enlarged and yellow.

Histology

- Multifocal deposition of clear (xanthomatous) cells throughout the involved tissue

Differential Diagnosis

- Lipid storage diseases
- Nonspecific tonsillitis

Fig. 9-19. Tangier disease.

A, Tonsillectomy specimen showing enlarged and slightly yellow-appearing tonsils. **B**, Deposition of xanthomatous cells in the tonsillar parenchyma.

Treatment and Prognosis

- Management is essentially symptomatic.
- To date, there is no specific treatment for Tangier disease:
 - Drugs known to increase HDL levels have been shown to be ineffective in Tangier patients.
 - Possible and more realistic therapeutic strategy designed to obtain selective increase of mature HDL concentration to restore cholesterol efflux
 - Recently designed drugs such as the cholesteryl ester transfer protein (CETP) inhibitors

dalcetrapib and anacetrapib and reconstituted forms of HDL could be considered until the development of gene therapy.

- Prognosis is good; however, coronary artery disease is common in patients over the age of 40 years of age.

Neoplasms of the Pharynx

CLASSIFICATION OF PHARYNGEAL NEOPLASMS

(Box 10-1)

General Considerations

- Similar to tumors of other upper aerodigestive tract sites, the most common tumors of the pharynx are of epithelial origin:
 - The most common benign neoplasm is a (squamous) papilloma.
 - The most common malignant neoplasm is squamous cell carcinoma or variant thereof.
- Unique carcinoma types identified in pharyngeal sites are the viral-associated head and neck squamous cell carcinomas, including:
 - Epstein-Barr virus (EBV)-associated squamous cell carcinoma typically localized to the nasopharynx
 - Human papillomavirus (HPV)-associated squamous cell carcinoma typically localized to the oropharynx (i.e., tonsil and base of tongue)
- Incidence of viral-associated head and neck squamous cell carcinoma, in particular the HPV-associated carcinoma, is increasing while the incidence of nonviral-associated HNSCC-related to tobacco and alcohol has stabilized and even is decreasing.

BOX 10-1 Classification of Neoplasms of the Pharynx, Including Nasopharynx, Oropharynx, and Hypopharynx

Benign

Epithelial

- Squamous papilloma
- Minor salivary gland tumors

Mesenchymal/Neuroectodermal

- Angiofibroma
- Craniopharyngioma
- Vascular neoplasms (e.g., hemangioma, lymphangioma)
- Peripheral nerve sheath tumors
- Paraganglioma
- Lipomas
- Rhabdomyomas
- Fibrous histiocytic tumors
- Leiomyomas
- Osseous and cartilaginous tumors
- Others

Malignant

Epithelial/Neuroendocrine

- Squamous cell carcinoma including:
 - Conventional-type and variants (e.g., verrucous carcinoma, papillary [exophytic] squamous cell carcinoma, spindle cell squamous carcinoma, basaloid squamous cell carcinoma, adenosquamous carcinoma, others)

- Viral-related head and neck squamous cell carcinomas
 - HPV-associated squamous cell carcinoma
 - EBV-associated squamous cell carcinoma
- Neuroendocrine carcinomas
- Minor salivary gland tumors
- Low-grade nasopharyngeal papillary adenocarcinoma
- Others

Hematolymphoid Malignant Neoplasms

- Non-Hodgkin lymphomas
- Hodgkin lymphoma
- Plasma cell neoplasms
- Others

Melanocytic/Mesenchymal/Neuroectodermal

- Mucosal malignant melanoma
- Rhabdomyosarcoma
- Synovial sarcoma
- Chordoma
- Reticulum dendritic cell sarcoma
- Leiomyosarcoma
- Liposarcoma
- Malignant peripheral nerve sheath tumors
- Vascular neoplasms (e.g., angiosarcoma, others)
- Teratocarcinosarcoma

Secondary Neoplasms

BENIGN NEOPLASMS

SQUAMOUS PAPILLOMA

(Fig. 10-1)

Definition: Benign, exophytic epithelial neoplasm composed of branching fronds of squamous epithelium with fibrovascular cores.

Synonym: Squamous cell papilloma

Clinical

- Most common benign neoplasm of the upper aerodigestive tract mucosa but involvement of the nasopharynx and oropharynx is uncommon

Fig. 10-1. Squamous papilloma of the pharynx.

A, Squamous papilloma of the tonsil appearing as an exophytic warty-looking lesion. **B**, Exophytic epithelial proliferation with fingerlike projections and fibrovascular cores. **C**, Papillary frond composed of a benign squamous epithelial proliferation devoid of surface keratosis. **D**, High magnification of cells with viral-associated changes (koilocytes) characterized by hyperchromatic, raisinoid-appearing nuclei with irregular nuclear contours; such papillomas are most often associated with low-risk HPV viruses including types 6, 11. **E**, By and large, squamous papillomas of the upper aerodigestive tract including those of the oropharynx are p16 negative.

- No gender predilection; most commonly seen in the third to fifth decades of life
- Any site can be affected but most frequently identified involving the tonsil and uvula
- Symptoms relate to a painless mass.
- Majority are solitary but occasionally may be multiple
- Viral (human papillomavirus [HPV]) cause:
 - No definitive association between HPV and the pharyngeal papillomas

Pathology

Gross

- Exophytic, pink to tan-white lesion with a warty or cauliflower-like appearance; variation in size from a few millimeters up to 3.0 cm in greatest dimension

Histology

- Multiple finger-like projections with prominent fibrovascular cores covered by hyperplastic squamous epithelium; typically there is an absence of keratosis:
 - Squamous cell component generally is free of any dysplastic change.
 - Variable amount of hyper-, para-, and orthokeratosis may be seen.
 - On rare occasions, an “inverted” growth may be seen.

Special Stains

- p16 immunohistochemical staining is negative.

Differential Diagnosis

- Verrucous carcinoma
- Exophytic squamous cell carcinoma

Treatment and Prognosis

- Conservative but complete surgical excision
- Recurrences occur infrequently and relate to inadequate excision.
- Malignant transformation not known to occur.

BENIGN MINOR SALIVARY GLAND NEOPLASMS

- Benign salivary gland neoplasms of the nasopharynx and oropharynx are uncommon but do occur.
- Virtually any benign or malignant salivary gland neoplasm may occur in the pharynx but:
 - Most common type is a pleomorphic adenoma
 - Less often, monomorphic adenomas including basal cell adenoma, myoepithelioma, and oncocytoma occur.

- The more common malignant minor salivary gland neoplasms of the pharynx include mucoepidermoid carcinoma and adenoid cystic carcinoma.
- For a more complete discussion see Section 2, Oral Cavity, and Section 6, Salivary Glands.
- Minor salivary gland neoplasms of the pharynx may appear as polypoid or exophytic growths, usually covered by an intact mucosa, and vary in size from 1 to 7 cm.
- Similar to minor salivary gland neoplasms of other upper aerodigestive tract, those of the pharynx, whether benign or malignant, are unencapsulated, but in contrast to malignant minor salivary gland tumors, benign minor salivary gland neoplasms are relatively circumscribed without invasive growth:
 - Often the initial diagnostic modality includes incisional biopsy, in which the neoplasm appears fragmented and often the fragments are entirely composed of the lesion without surrounding tissues; given the overlapping light microscopic findings (growth pattern, cell types) and immunoreactivity shared by the more common types of benign and malignant minor salivary gland neoplasms, in this setting:
 - Without unequivocal evidence of invasive growth, differentiation between a benign from malignant minor salivary gland neoplasm cannot be achieved.
 - S100 protein evaluating for the presence or absence of perineural invasion is useful as arguably the sole immunostain in this scenario; the absence of perineural invasion by light microscopy and S100 protein staining does not exclude a diagnosis of carcinoma.
 - Using the designation “minor salivary gland neoplasm, not further specified” is appropriate with the recommendation for conservative but complete resection to include tumor-free margins.
 - Following complete excision with availability of surrounding tissues to evaluate for the presence or absence of invasive growth, a definitive diagnosis should be achievable.
 - Involvement of surface epithelium does not constitute invasion.
- Surgical excision is the preferred treatment for all types of benign minor salivary gland tumors.
- Surgery is usually curative, with local recurrence being seen in less than 10% of patients:
 - Recurrent tumors are generally due to incomplete (initial) excision.

Fig. 10-2. Angiofibroma.

Clinical appearance of nasopharyngeal angiofibroma may include **(A)** lobulated, red-pink (vascular-appearing) mass or **(B)** tan-white (fibrous-appearing) mass. Both lesions originated from the posterolateral wall of the nasal cavity near the sphenopalatine foramen extending into the nasopharynx and oropharynx.

(NASOPHARYNGEAL) ANGIOFIBROMA

(Figs. 10-2 through 10-4)

Definition: Benign neoplasm composed of an admixture of mature vascular and fibrous tissue with locally destructive properties.

Synonyms: Juvenile angiofibroma; angiofibroma

NOTE: Evidence suggests that this tumor does not originate from the nasopharynx but rather from a fibro-vascular nidus in the posterolateral wall of the nasal cavity near the sphenopalatine foramen secondarily

Fig. 10-3. Angiofibroma.

Juvenile nasopharyngeal angiofibroma (JNA) in a 14-year-old boy with chronic nasal obstruction and epistaxis.

A, Axial, contrast-enhanced, T1-weighted, MR image shows an intensely enhancing tumor filling the right nasal cavity and deviating the nasal septum. The pterygopalatine fossa and pterygomaxillary fissure are widened and filled with tumor (*arrows*). There is anterior displacement of the posterior wall of the right maxillary antrum. **B,** The coronal, contrast-enhanced, T1-weighted image reveals flow voids within the tumor (*open arrow*). The cephalad extent of the tumor is well seen on the coronal images. There are retained secretions within the sphenoid sinus (*arrow*).

(From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Figure 30-106, p 1883.)

Fig. 10-4. Nasopharyngeal angiofibroma.

A through D, The tumor is composed of a variable admixture of blood vessels and fibrous tissue. The vascular component is composed of thin-walled blood vessels varying in appearance from stellate to staghorn to inconspicuous due to marked compression by stromal fibrous tissue; vessel walls are lined by flattened to plump endothelial cells forming a single layer and have an incomplete smooth muscle layer appearance. Stromal cells have spindle-shaped to stellate to plump nuclei with variable collagenized stroma. Immunohistochemical staining shows the spindle cells to be reactive for **(E)** β -catenin (nuclear staining) and **(F)** androgen receptor (nuclear staining).

Fig. 10-4, cont'd

G, Intravascular foreign material with associated multinucleated (foreign body type) giant cells represents evidence of preoperative embolization in the attempt to infarct the tumor.

extending into the nasopharynx and other adjacent/contiguous anatomic sites:

- Given the presumed origin in the posterior nasal cavity, the use of the designation “nasopharyngeal” is questioned.
- These tumors are not strictly limited to juvenile ages so that the use of the designation “juvenile” is not recommended.

Clinical

- Relatively rare neoplasm accounting for less than 1% of all head and neck tumors
- Occurs almost exclusively in men, and some believe that it is a tumor limited to the male population; occurs over a wide age range but are most common in the second decade of life:
 - Uncommon over the age of 25 years
 - May occur in older ages, thereby negating the use of the designation “juvenile” angiofibroma
- Most common clinical complaints are persistent nasal obstruction and epistaxis:
 - Late signs and symptoms include facial swelling or deformity (swelling of the cheek), nasal discharge, proptosis, diplopia, headache, sinusitis, cranial nerve palsies, anosmia, and hearing deficits.
 - Pain may occur but is considered an unusual finding.
 - Typically, symptoms have been present for more than 1 year prior to diagnosis.
- Site of occurrence is usually the posterolateral portion of the roof of the nasal cavity in the area of the sphenopalatine foramen:
 - Large tumors may extend anteriorly into the nasal cavity, causing nasal obstruction and

simulating a primary intranasal or paranasal sinus tumor.

- Extension posteriorly may fill the nasopharynx and extend into the oropharynx, causing displacement of the soft palate.
- Extension can occur through the sphenopalatine foramen with involvement of the pterygomaxillary fossa and infratemporal fossa, resulting in facial deformities.
- Extension into the middle cranial fossa can occur if the tumor involves and destroys the pterygoid process.
- As a result of the overwhelming occurrence in males, this tumor is thought to be hormonally driven, being dependent on testosterone and inhibited with estrogen:
 - Androgen receptors have been found in these tumors but not estrogen receptors.
- Familial predisposition suggested in patients with familial adenomatous polyposis (FAP):
 - FAP results from germline mutations in the adenomatous polyposis coli (*APC*) gene that subsequently alters the β -catenin signaling pathway.
 - Patients with FAP develop nasopharyngeal angiofibroma 25 times more frequently than an age-matched population.
 - Role for the *APC*– β -catenin pathway has been suggested in patients with nasopharyngeal angiofibroma with the *APC* gene mutation.
 - Activating β -catenin mutation without the *APC* gene mutation has been reported in sporadic nasopharyngeal angiofibroma.
 - Immunohistochemical findings support the role of β -catenin in nasopharyngeal angiofibromas:
 - Expression of β -catenin, c-kit (CD117), and neural growth factor (NGF) higher and more frequent in stromal cells of nasopharyngeal angiofibromas than those of nasal polyps
 - Potential involvement of c-kit and neural growth factor (NGF) signaling pathways in the nasopharyngeal angiofibromas has been suggested.
 - Although the biologic significance of c-kit in nasopharyngeal angiofibromas has not been defined, the finding of frequent and high c-kit expression may have therapeutic importance.
 - In spite of the above findings, the association with nasopharyngeal angiofibroma and FAP has been disputed based on the absence of detectable mutations in *APC* gene in patients with nasopharyngeal angiofibroma.
- In a limited number of patients, consumptive coagulopathy has been found as a complication of nasopharyngeal angiofibromas, suggesting that

TABLE 10-1 Radiographic Staging of Nasopharyngeal Angiofibroma

Stage	Extent of Disease
I	Limited to nasopharynx with no bone destruction
II	Invasion into nasal cavity, maxillary, ethmoid or sphenoid sinuses with no bone destruction
III	Invasion of pterygopalatine fossa, infratemporal fossa, orbit, or parasellar region
IV	Massive invasion of the cranial cavity, cavernous sinus, optic chiasm, or pituitary fossa

preoperative coagulation studies may be useful in ensuring perioperative hemostasis.

- Radiology:
 - Routine radiographs show characteristic bowing of the posterior wall of the maxillary antrum, as well as distortion and posterior displacement of the pterygoid plates (Holman-Miller sign).
 - CT scan with contrast enhancement demonstrates the mass and its extension into adjacent areas.
 - Arteriographic findings are usually diagnostic and include a tumor with marked vascular hypertrophy and increased number of arteries without beading, dilatation, segmental narrowing, or aneurysmal dilatation.
 - Blood supply may be uni- or bilateral and typically comes from branches of the external carotid artery (internal maxillary or ascending pharyngeal branches).
 - Intracranial extension should be considered in cases where the internal carotid artery is the dominant vascular supply.
 - Various radiographic staging systems for nasopharyngeal angiofibroma based on extent of disease have been proposed (Table 10-1), with the two most often used proposed by Sessions (Table 10-2), which was subsequently modified by Radowski (Table 10-3).

Pathology

Gross

- May appear as sessile or lobulated masses but may occasionally be polypoid or pedunculated

Histology

- Unencapsulated and characterized by a fibrocollagenous stromal proliferation with an admixture of variably sized vascular spaces
- Vascular component is composed of thin-walled, small to large vessels varying in appearance from stellate or staghorn to barely conspicuous due to marked compression by stromal fibrous tissue.

TABLE 10-2 Sessions Staging of Nasopharyngeal Angiofibroma

Stage	Extent of Disease
IA	Tumor limited to posterior nares and/or nasopharyngeal vault; no paranasal sinus extension
IB	Same as IA but with extension into one or more paranasal sinuses
IIA	Minimal lateral extension through the sphenopalatine foramen, into and including a minimal part of the medialmost part of the pterygomaxillary fossa
IIB	Full occupation of pterygomaxillary fossa, displacing the posterior wall of the maxillary antrum forward. Lateral and/or anterior displacement of branches of the maxillary artery. Superior extension may occur, eroding the orbital bones
IIC	Extension through the pterygomaxillary fossa into the cheek and temporal fossa
III	Intracranial extension

Sessions RB et al: Radiographic staging of juvenile angiofibroma, *Head Neck Surg* 3:279-283, 1981.

TABLE 10-3 Modified (Radkowski) Staging of Nasopharyngeal Angiofibroma

Stage	Extent of Disease
IA	Limited to posterior nares and/or nasopharyngeal vault
IB	Tumor involving the posterior nares and/or nasopharyngeal vault with involvement of at least one paranasal sinus
IIA	Minimal lateral extension into pterygomaxillary fossa
IIB	Full occupation of pterygomaxillary fossa with or without superior erosion orbital bones
IIC	Extends into the infratemporal fossa or extension posterior to the pterygoid plates
IIIA	Erosion of base of skull (middle cranial fossa/base of pterygoids) – minimal intracranial extension
IIIB	Extensive intracranial extension with or without extension into cavernous sinus

Modified from Nicolai P, Schreiber A, Bolzoni Villaret A: Juvenile angiofibroma: evolution of management. *Int J Pediatr* 2012;412545, 2012.

- Endothelial cells form a single layer and are flat or plump in appearance.
- Vessel walls lack elastic fibers and are distinctive in having a smooth muscle layer which may be incomplete or discontinuous and which shows marked variation in thickness.

- Central aspects of the tumor may be relatively hypovascular.
- Stroma is composed of fibrous tissue with fine or coarse collagen fibers.
- Stromal cells are spindle-shaped and stellate with plump nuclei, and they tend to radiate around vessels.
- Nuclear pleomorphism and multinucleated giant cells may be seen; mitotic figures are rare.
- Stroma may be focally myxoid.
- Mast cells are common; however, other inflammatory cells are absent except near areas of surface ulceration.
- Evidence of preoperative embolization may be seen in tissue sections in the form of intravascular fibrin thrombi containing foreign material and tumor infarction.
- Tumors of longer duration tend to be more fibrous and less vascular.
- Immunohistochemistry:
 - Endothelial cells within the vascular spaces are reactive with:
 - Endothelial cell markers (e.g., CD31, Factor VIII–related antigen, CD34, others)
 - Smooth muscle actin-positive cells can be found around the circumference of the vascular spaces.
 - Spindle-shaped and stellate stromal cells are:
 - Vimentin positive
 - Nuclear β -catenin staining
 - Nuclear androgen receptor and testosterone positive
 - Estrogen and progesterone receptor negative
 - S100 protein negative
- Nonsurgical management has been proposed, including estrogen therapy, use of testosterone-receptor blockers such as flutamide, or radiation therapy:
 - These treatment modalities reduce the angiomatous component of the tumor and may be used in patients whose tumors are deemed unresectable.
- Complications associated with angiofibromas include excessive bleeding, recurrence of tumor, and extension of the tumor beyond the nasopharynx to involve adjacent anatomic compartments (sinonasal cavities, oropharynx, pterygomaxillary fossa, superior buccal sulcus, orbit, infratemporal fossa, and cranial cavity).
- Given their propensity to bleed, biopsies of the tumor should be performed with extreme caution.
- Recurrence rates vary from 6% to as high as 24%:
 - High recurrence rates and early recurrence may occur in nasopharyngeal angiofibromas involving the skull base.
 - Early postoperative contrast-enhanced helical CT is an accurate tool to evaluate excision of in the days after surgery.
 - Recurrences are more common in cases with intracranial extension.
 - Tumor recurrence in cases without intracranial extension usually occurs within 2 years of treatment.
- In general, the prognosis is excellent following surgical removal:
 - Mortality rates range from 3% to 9%.
 - Rarely, spontaneous regression may occur.
 - Malignant (sarcomatous) transformation is a rare event and has been linked to treatment with radiotherapy (post-irradiation sarcomas).

Differential Diagnosis

- Inflammatory nasal polyps
- Antrochoanal polyp
- Lobular capillary hemangioma
- Peripheral nerve sheath tumors
- Aggressive (desmoid) fibromatosis

Treatment and Prognosis

- In uncomplicated cases (with tumor limited to the nasopharynx), surgical excision via a transverse palatal approach is the preferred treatment.
- Vascular embolization usually precedes surgical intervention to control bleeding.
- Over the past two decades there has been a marked shift to less invasive endonasal approaches/procedures while the tumor stages of the patients treated remained the same.
- Successful management using less invasive techniques has been achieved with reduction in morbidity and without increasing the chance of recurrence.

CRANIOPHARYNGIOMA

(Figs. 10-5 and 10-6)

Definition: Rare benign epithelial tumor of the sellar region presumably derived from Rathke pouch epithelium.

Synonyms: Rathke pouch tumor; craniopharyngeal duct tumor; pituitary adamantinoma

- Considered to be a World Health Organization grade I (central nervous system) neoplasm (WHO grade I)

Clinical

- Most common non-neuroepithelial intracerebral neoplasm in children accounting for 5% to 10% of pediatric intracranial tumors
- Two clinicopathologic forms:
 - Adamantinomatous craniopharyngioma
 - Papillary craniopharyngioma

Fig. 10-5. Craniopharyngioma, adamantinomatous type.

A and B, Cellular proliferation with solid, cystic, and trabecular growth composed of multistratified squamous epithelium with peripheral palisading of nuclei resting on the basement membrane and foci showing a looser arrangement of the cells (stellate reticulum). **C,** Eosinophilic keratinized cells with ghost nuclei and associated calcification ("wet keratin") is present. **D,** Cholesterol granuloma formation is a common finding appearing as clear slit-like spaces with associated multinucleated giant cells (center and bottom of image); note the presence of foci of "wet keratin" (arrows) composed of eosinophilic acellular material with associated multinucleated giant cells as well as the presence of foamy histiocytes (top center).

- Adamantinomatous craniopharyngioma:
 - Slightly more common in males than females; bimodal age distribution including 5 to 14 years and adults over age 45 to 60 years
 - Most frequent is suprasellar with an intrasellar component
 - 20% restricted to suprasellar region
 - 5% entirely intrasellar
 - Extension of tumor may occur anteriorly into the middle cranial fossa and retroclival
 - Ectopic locations occur and include:
 - Optic nerves, pineal region, sphenoid bone, nasopharynx, and cerebellopontine angle
 - Symptoms include:
 - Visual disturbances:
 - More frequent in adults
 - Include loss of central vision
 - Headache
 - Endocrine deficiencies:
 - More common in children
 - More commonly seen in association with the papillary variant
 - Include deficiencies in growth hormone (75%), luteinizing hormone and/or follicle-stimulating hormone (40%), adrenocorticotrophic hormone (25%), and thyroid-stimulating hormone (25%)

Fig. 10-6. Papillary craniopharyngioma.

Craniopharyngioma, papillary type, composed of sheets of well-differentiated squamous epithelium that separate to form pseudopapillae with anastomosing fibrovascular stroma; the epithelial proliferation lacks surface maturation, peripheral palisading, stellate reticulum, calcifications, wet keratin, and cholesterol clefts that are seen in adamantinomatous craniopharyngiomas.

- Diabetes insipidus noted in 17% of children and up to 30% of adults
- Dementia:
 - Cognitive impairment and personality changes occur in approximately 50% of patients.
- Radiology:
 - Adamantinomatous variant appears as a calcified, solid, and cystic mass:
 - CT scan:
 - Contrast enhancement of solid portions of the cyst capsule

- T1-weighted MRI:
 - Cystic areas appear well delineated, homogeneous, and hyperintense.
 - Solid components and mural nodules are iso-intense with heterogeneous aspect.
- T2-weighted MRI:
 - Cystic portion is iso-intense with an enhancing ring.
 - Solid component is hyperintense.
- Papillary craniopharyngioma:
 - No gender predilection; occurs almost exclusively in adults
 - Usually involves the third ventricle
 - Symptoms include:
 - Vision loss
 - Increased intracranial pressure
 - Diminished mental acuity and personality changes
 - Endocrine deficiencies (see above under adamantinomatous craniopharyngioma)
 - Radiology:
 - Noncalcified, vary from solid to cystic
 - More uniform appearance in CT and MRI than adamantinomatous craniopharyngioma
- Nasopharynx represents most common purely extra-sellar location for craniopharyngiomas:
 - Ectopic localization in the nasopharynx may be associated with headache, nasal obstruction epistaxis, or impaired vision.
 - Exceptionally may occur in the sinonasal tract:
 - Sphenoid sinus, maxillary sinus, ethmoid sinus
 - Multiple simultaneous sites of occurrence may be identified, including nasopharynx, sella turcica, and sinonasal tract.

Pathology

- Adamantinomatous craniopharyngioma (similar to ameloblastoma and calcifying odontogenic cyst):
 - Nodular and multicystic
 - Solid, nests, cords, strands, or anastomosing trabeculae of multistratified squamous epithelium with peripheral palisading of nuclei resting on the basement membrane, intercellular bridges, keratin pearls, and (dystrophic) calcification
 - Central aspects of the tumor nests/cords show a looser arrangement of the cells (stellate reticulum).
 - So-called wet keratin composed of eosinophilic keratinized cells with ghost nuclei and associated calcification
 - Cyst lining cells may include columnar basaloid cells and/or flattened stratified squamous epithelium.
 - Cholesterol clefts/deposits

- Papillary craniopharyngioma:
 - Sheets of squamous epithelium that separate to form pseudopapillae with anastomosing fibrovascular stroma:
 - Epithelium separates to form crude pseudopapillae.
 - Typically lacks surface maturation, peripheral palisading, stellate reticulum, calcifications, wet keratin, and cholesterol clefts
 - Ciliated epithelium and goblet cells may focally be present.
- Cytogenetics and molecular genetics:
 - A molecular hallmark of adamantinomatous craniopharyngioma is the activated Wnt signaling pathway indicated by nuclear β -catenin accumulation in a subset of tumor cells.
 - β -catenin nuclear translocation may occur in the absence of CTNNB1 mutations, suggesting that other genetic or epigenetic events can activate Wnt signaling in adamantinomatous craniopharyngioma.

Differential Diagnosis

- Ameloblastoma:
 - Histologic similarities exist between ameloblastoma and craniopharyngioma, and rare occurrence of a (peripheral) ameloblastoma in the nasopharynx and rare occurrence of craniopharyngioma in infratemporal (e.g., nasopharyngeal) locations may result in differential diagnostic difficulties.
 - Other than anatomic location, there are no specific findings differentiating craniopharyngioma from ameloblastoma.

Treatment and Prognosis

- Surgical resection is the preferred treatment for both types of craniopharyngiomas irrespective of location.
- Slow-growing, benign tumor that may have locally aggressive behavior but no tendency to metastasize
- Due to location and potential involvement of vital structures, complete surgical resection may prove challenging, resulting in:
 - Local recurrence in approximately 20% to 50%
 - Need for adjuvant radiotherapy
- Survival rates include:
 - Overall 5-year survival of 80% but negatively affected by increasing age:
 - 99% for under 20 years
 - 79% for 20 to 64 years
 - 37% for 65 years and older
 - 10-year recurrence-free survival of 60% to 93%
 - 10-year overall survival of 64% to 96%
- Purported better prognosis reported for the papillary rather than adamantinomatous type but such findings not substantiated in the literature
- Malignant transformation to squamous cell carcinoma following radiotherapy is an extraordinarily rare occurrence:
 - p53 overexpressed in the malignant component
 - p53 expression much lower in the benign component
- De novo malignant craniopharyngioma (i.e., not developing from a previously treated benign craniopharyngioma) may (extraordinarily) rarely occur
- Radiation-induced gliomas reported following treatment of craniopharyngioma

MALIGNANT TUMORS

EPITHELIAL MALIGNANT NEOPLASMS

Squamous Cell Carcinoma (SCC) of the Pharynx, Including Nasopharynx, Oropharynx, and Hypopharynx

General Considerations

- Etiologic factors linked to the development of pharyngeal carcinomas vary per site and include:
 - Oncogenic viruses, including Epstein-Barr virus (EBV) and human papillomavirus (HPV):
 - Epstein-Barr virus (EBV):
 - Found in association with nasopharyngeal carcinomas, in particular nonkeratinizing differentiated and undifferentiated types

- For more complete discussion see later in this chapter
- Human papillomavirus (HPV):
 - Found in association with oropharyngeal carcinomas, in particular carcinomas originating from the tonsil and base of tongue
 - Nonkeratinizing histomorphology
 - For more complete discussion see later in this chapter
- Tobacco and alcohol:
 - Tobacco use/abuse includes smoking and chewing (smokeless tobacco)
 - Alcohol potentiates the carcinogenic effect of tobacco
 - Linked to cancers of the hypopharynx as well as keratinizing carcinomas of the nasopharynx and oropharynx

- Still represents a significant risk factor in oropharyngeal carcinomas

Viral-Related Head and Neck Squamous Cell Carcinomas

- Increasing evidence that Epstein-Barr virus (EBV) and human papillomavirus (HPV) play a pathogenic role in a subset of pharyngeal head and neck squamous cell carcinomas (HNSCC).
- Viral-related HNSCCs may be termed:
 - EBV-associated head and neck squamous cell carcinoma (EBV-HNSCC)
 - HPV-associated head and neck squamous cell carcinoma (HPV-HNSCC)
 - Such designations are not as yet universally accepted but have merit given the unique clinical, pathologic, therapeutic, and prognostic implications associated with these cancers.
- For nasopharyngeal carcinomas (NPC):
 - EBV is associated with the nonkeratinizing types of nasopharyngeal carcinomas, including differentiated and undifferentiated subtypes:
 - Consistent (near 100%) association in Asian populations
 - Less consistent association in Caucasian populations which, in a significant proportion of cases, may be associated with HPV
 - Most reliable detection method for EBV is in situ hybridization for EBV encoded early RNA (EBER) present in cells latently infected by EBV and can facilitate the diagnosis of NPC.
- For oropharyngeal carcinomas:
 - HPV, in particular, the high-risk type 16 (HPV-16), is present in most oropharyngeal carcinomas (i.e., base of tongue, tonsils).
 - For those oropharyngeal cancers positive for high-risk HPV, HPV-16 is detected in more than 90% of cases.
 - p16 immunohistochemical staining is a reliable and sensitive surrogate marker for HPV-16.

Nasopharyngeal Carcinoma (NPC)

Definition: NPC is a squamous cell carcinoma originating from the nasopharyngeal mucosa showing evidence of squamous differentiation by light microscopy, immunohistochemistry, or electron microscopy.

Nomenclature: NPC is classified according to the World Health Organization (WHO) into two histologic variants:

1. Keratinizing type (well, moderately, and poorly differentiated)

BOX 10-2 World Health Organization (WHO) Classification of Nasopharyngeal Carcinoma (NPC)

WHO Type I

- Keratinizing squamous cell carcinoma

WHO Type II

- Nonkeratinizing differentiated
- Nonkeratinizing undifferentiated
- Basaloid squamous cell carcinoma

2. Nonkeratinizing, which is further subdivided into:
 - Differentiated type
 - Undifferentiated type
- Current WHO classification retains the terminology of the 1991 classification and adds the category of basaloid squamous cell carcinoma to this classification (Box 10-2).
- Prior numeric designations of WHO types 1 (squamous cell carcinoma), 2 (nonkeratinizing carcinoma), and 3 (undifferentiated carcinoma) are no longer used.
- Use of the designation nasopharyngeal carcinoma is to the exclusion of all other malignant tumors that may arise in this region, including adenocarcinomas (minor salivary gland origin and nonsalivary gland origin).

Synonyms: EBV-associated head and neck squamous cell carcinoma; EBV-associated carcinoma; lymphoepithelioma, Rigaud and Schmincke types of lymphoepitheliomas; transitional carcinoma

NOTES:

- The designation lymphoepithelioma is a misnomer; this is a tumor entirely of epithelial origin with a secondary associated benign lymphoid component. Use of the term lymphoepithelioma may result in confusion with a diagnosis of malignant lymphoma.
- Rigaud and Schmincke refer to patterns of growth and have no practical significance in the diagnosis, treatment, or prognosis of NPC.
- Although they share the unfortunate designation of “undifferentiated,” as well as overlapping histomorphologic features, there is no relationship between the sinonasal undifferentiated carcinoma (see Section 1, Sinonasal Tract) and the nasopharyngeal carcinoma, nonkeratinizing undifferentiated type:
 - These two tumor types are anatomically distinct with differing therapeutic approaches, biologic outcomes, and causes:
 - Nasopharyngeal carcinoma nonkeratinizing types are associated with EBV.
 - Sinonasal undifferentiated carcinoma (SNUC) is not associated with EBV.

TABLE 10-4 Nasopharyngeal Carcinoma (NPC)

	Keratinizing	Nonkeratinizing, Differentiated	Keratinizing, Undifferentiated
Percent	Approximately 25%	Least common <15%	Most common >60%
Sex/Age	M > F; 4th-6th decades	M > F; 4th-6th decades	M > F; 4th-6th decades; may occur in children
Histology	Keratinization, intercellular bridges; conventional squamous carcinoma graded as well, moderately or poorly differentiated; desmoplastic response to invasion	Little to absent keratinization, growth pattern interconnecting cords (similar to transitional urothelial carcinoma); typically, limited to absent desmoplastic response to invasion	Absence of keratinization, syncytial growth, cohesive or noncohesive cells with round nuclei, prominent eosinophilic nucleoli, scant cytoplasm, and limited mitoses; prominent non-neoplastic lymphoid component; typically, absence of desmoplastic response to invasion
EBV	Weak association	Strong association	Strong association
Treatment	Radio-responsiveness is not good	Radioresponsive	Radioresponsive
Prognosis	20% to 40% 5-year survival	75% 5-year survival	75% 5-year survival

Clinical (Table 10-4)

- Overall, NPC is an uncommon neoplasm in the United States, accounting for approximately 0.25% of all cancers:
 - In China, NPC accounts for 18% of all cancers, and 1 in 40 men develop NPC before the age of 72 years.
- Affects men more than women; occurs over a wide age range but is most common in the fourth to sixth decades of life:
 - Less than 20% of cases occur in pediatric age groups.
 - Pediatric NPC is most common in northern and central Africa, accounting for 10% to 20% of all cases, whereas only approximately 2% of NPC in China occurs in children.
- Signs and symptoms are often subtle and nonspecific and thereby may cause a delay in the diagnosis, resulting in clinical presentation at an advanced stage of disease.
- Clinical presentation may include:
 - Presence of an asymptomatic cervical neck mass typically localized to the posterior cervical triangle or the superior jugular nodal chain:
 - Can be present in up to 50% of patients as initial presentation for NPC
 - Primary carcinoma often occult
 - No correlation to size of primary NPC, which may be extremely small (millimeters), and size of nodal metastasis, which may be large (centimeters)
 - Bilateral cervical neck metastasis may be seen in up to 25% of cases.
 - A finding associated with WHO nonkeratinizing types of NPCs but typically not seen in association with WHO keratinizing types of NPCs.
 - Additional clinical signs and symptoms include nasal obstruction, nasal discharge, epistaxis, pain, serous otitis media, otalgia, hearing loss, and headache.
- Up to 25% of patients may experience cranial nerve involvement:
 - Cranial nerve involvement occurs by spread of tumor laterally through the cavernous sinus, with involvement of cranial nerves III, IV, ophthalmic branch of V and VI, and by direct tumor extension with involvement of cranial nerves IX, X, XI, XII and the third division of V nerve through the parapharyngeal space in proximity to the lateral nasopharyngeal wall.
- Lateral wall of the nasopharynx (fossa of Rosenmüller) is the most common site of occurrence followed by the superior posterior wall:
 - May result in unilateral otitis media and conductive hearing loss due to obstruction of the orifice of the eustachian tube opening into the lateral wall of the nasopharynx
 - Anecdotally, unilateral otitis media in an adult unresponsive to antibiotic therapy is NPC until proven otherwise.
- Radiology (Figs. 10-7 and 10-8):
 - Represents an important diagnostic aid in assessing the extent of disease and presence of metastatic disease
 - Magnetic resonance imaging (MRI) is the preferred study to computed tomography (CT) for the detection of invasion into soft tissues, intracranial extension, and invasion into bone:
 - Care must be taken with fat suppression because this often produces artifacts at air-bone interfaces at the skull base.
 - CT is very good for showing cortical bone erosion.

Fig. 10-7. Nasopharyngeal carcinoma.

A, Axial T1 precontrast MR image through an infiltrating right-sided nasopharyngeal mass (*arrows*). **B**, Axial T2-weighted image shows that the mass (*arrows*) extends laterally to involve the lateral pterygoid muscle, indicating a T4b lesion. Note the normal left lateral pterygoid muscle (*P*). **C**, T1-weighted, fat-suppressed, contrast-enhanced image demonstrates contrast enhancement of the tumor (*M*). This patient had a nasopharyngeal carcinoma. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Figure 29-2, p 1751.)

Fig. 10-8. Nasopharyngeal carcinoma.

Axial PET/CT scan shows a primarily left-sided nasopharyngeal mass that has spread along the mucosa to the right side. The standard uptake value of this tumor was 19. Also seen is a high right level IIB node. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Figure 29-11, p 1757.)

- In addition to other imaging studies (e.g., conventional x-ray, ultrasound, computed tomography), positron emission tomography and computed tomography (PET-CT) are used in the detection of locoregional and distant spread of tumor.
- Multiple interactive etiologic factors have been linked to the development of NPC:
 - Genetic and geographic factors play an important role in the genesis of NPC:
 - Increased incidence of NPC in China, especially in southern (Kwantung province) and northern provinces and Taiwan
 - Although the incidence among Chinese people decreases after emigration to low-incidence areas, it remains higher than in non-Chinese populations.
 - HLA-A2, HLA-B17, HLA-Bw46, and HLA-BW58 histocompatibility loci have been suggested as the marker for genetic susceptibility to nasopharyngeal carcinoma.
 - Most important link to the development of NPC is the Epstein-Barr virus (EBV):
 - There is a strong association between nasopharyngeal nonkeratinizing carcinomas (differentiated and undifferentiated types) and the presence of EBV, indicating an oncogenic role of EBV in the development of NPC.
- Elevated titers of IgA antibodies (against viral capsid antigen [VCA]) and IgG antibodies (against early antigen [EA]) are seen in patients with NPC, with detection rates for NPC ranging up to 93%.
- Elevated titers have been used as a marker to screen populations in high-risk areas and as a potential indicator of disease relapse.
- Positive serology against EBV in 90% of patients with nonkeratinizing carcinoma has been reported.
- Newer antibody tests based on recombinant EBV antigens (e.g., EBV nuclear antigens [EBNA], membrane antigen [MA], others) have been used in the diagnosis of NPC as has quantitative PCR to test for elevated circulating EBV DNA in plasma and serum and have reported sensitivity rates in NPC of up to 96%.
- Molecular biologic analysis of NPC by either in situ hybridization or polymerase chain reaction (PCR) detects EBV DNA or RNA in from 75% to 100% of NPC:
 - This fact is not true of the keratinizing subtype, in which the detection of EBV genomes is variable and, if present, is generally limited to scattered dysplastic intraepithelial cells.
- EBV is an early initiating event in the development of NPC:
 - EBV has been found in preinvasive (precursor) nasopharyngeal lesions, and the EBV-DNA identified was clonal, suggesting that the preinvasive lesions arose from a single EBV-infected cell, and that these preinvasive lesions progressed to invasive cancer within 1 year.
- EBV infection in NPC shows expression of EBV nuclear antigen-1 (EBNA-1) and latent membrane protein-1 (LMP-1) with an abundance of EBV encoded early RNAs (EBERs).
- Elevated levels of circulating cell-free Epstein-Barr virus (EBV) DNA detected in plasma and serum samples from NPC patients:
 - Good sensitivity and specificity and might be helpful for the screening of NPC
- Human papillomavirus (HPV) has been reported in nasopharyngeal carcinomas of keratinizing and nonkeratinizing types:
 - HPV may have a pathogenetic role for some nasopharyngeal carcinomas.
 - HPV-associated nasopharyngeal cancers may be morphologically similar to the EBV-associated carcinomas but are negative for EBER and positive for p16.
 - Tend to occur in nonendemic populations, including Caucasians with history of smoking

- Other suggested factors implicated in NPC include diet (salted fish high in nitrosamines), poor hygiene, and nondietary environmental factors, including atmospheric agents such as dust, smoke, chemical fumes, domestic smoke from burning wood, grass, and incense, and inhalation (active or passive) of tobacco smoke, the use of herbal medicines, and the use of nasal inhalants in the treatment of nasal disease.

Pathology

Gross

- Varies from a mucosal bulge with an overlying intact epithelium to a clearly demonstrable mass with extensive involvement of the surface epithelium and/or frankly infiltrative to a totally unidentifiable lesion fortuitously sampled and identified by microscopic evaluation

Histology

Nasopharyngeal Carcinoma, Keratinizing Type (Fig. 10-9)

- Represents approximately 25% of all NPC and rarely occurs in patients under 40 years of age
- Characterized by the presence of keratinization and intercellular bridges and graded as well, moderately, or poorly differentiated

- A desmoplastic response is typically found in response to invasive growth by this histologic type of NPC.

Nasopharyngeal Carcinoma, Nonkeratinizing Differentiated Type (Fig. 10-10)

- Least common type of NPC, representing approximately 12% of all NPC
- Growth includes the presence of interconnecting cords or trabeculae
- Predominantly nonkeratinizing stratified cellular proliferation with absent to focal keratinization and interconnecting and ramifying cords with sharp delineation from the surrounding stroma
- Well-defined cell borders and vague intercellular bridges may be present; in any given case foci of keratinization may be present.
- Typically, there is an absence of a desmoplastic response to invasive growth.
- Highly associated with EBV
- May undergo cyst formation with associated necrosis:
 - May metastasize as cystic metastatic nonkeratinizing carcinoma to cervical neck region
 - Overall histologic features similar if not identical to oropharyngeal nonkeratinizing (HPV-associated) squamous cell carcinoma

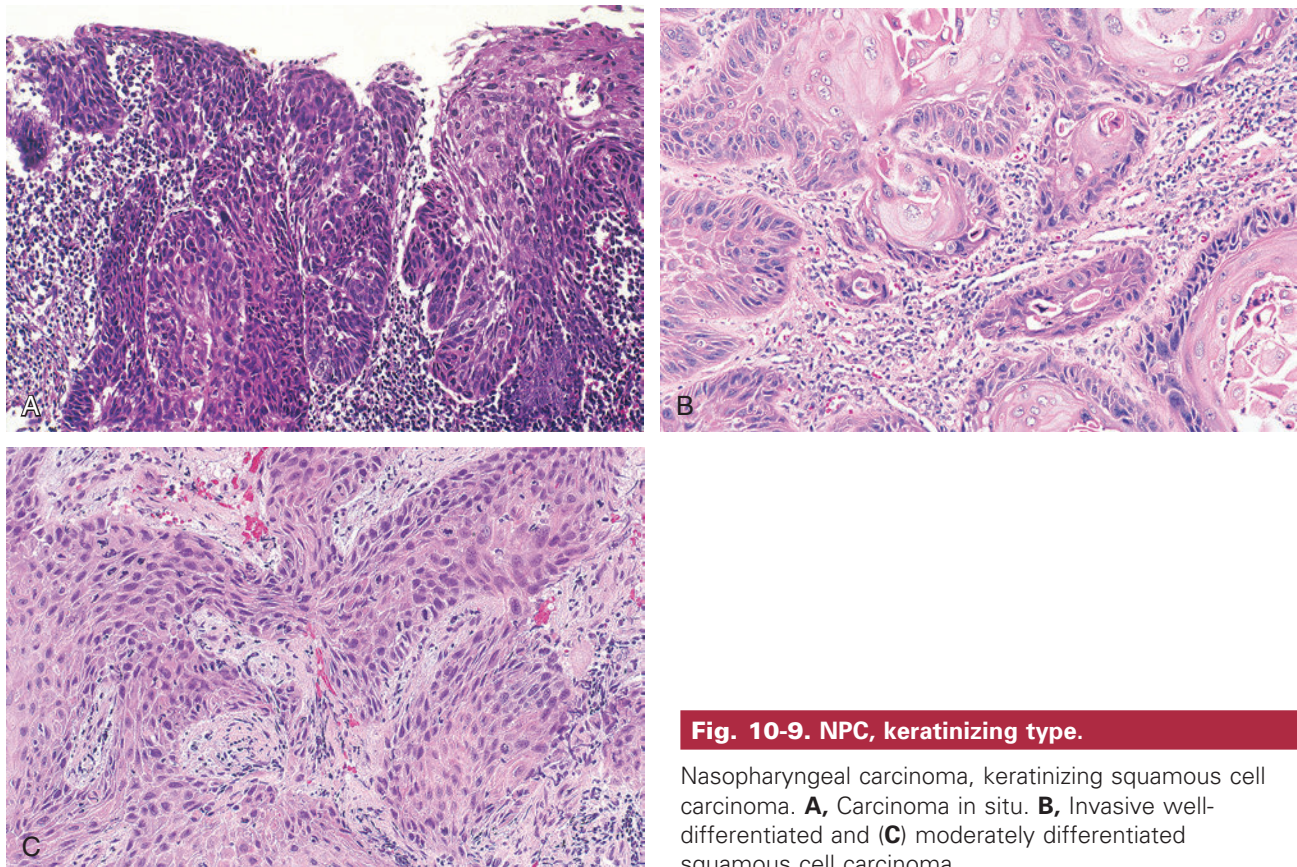

Fig. 10-9. NPC, keratinizing type.

Nasopharyngeal carcinoma, keratinizing squamous cell carcinoma. **A**, Carcinoma in situ. **B**, Invasive well-differentiated and (**C**) moderately differentiated squamous cell carcinoma.

Fig. 10-10. Nasopharyngeal carcinoma, nonkeratinizing differentiated.

A, Carcinoma in situ. **B** and **C**, Interconnecting cords and trabeculae of infiltrative carcinoma originating from the surface epithelium and maintaining this pattern of growth in its depth. **D**, Higher magnification showing stratified cells delineated from the surrounding stroma with absent keratinization and increased mitotic activity. **E**, Cystic degeneration showing cyst filled with necrotic material (*bottom right*). This carcinoma may metastasize to cervical lymph nodes as cystic metastatic nonkeratinizing carcinoma from an occult primary carcinoma. The overall histologic features are similar if not identical to oropharyngeal nonkeratinizing (HPV-associated) squamous cell carcinoma. Differentiation predicated on the presence or absence of EBER and p16. **F**, Lesional cells are EBER positive (nuclear staining).

- Presence of EBER and absence of p16 confirm diagnosis and generally would establish nasopharynx as primary source for such metastatic carcinoma; however:
 - Examples of nasopharyngeal carcinoma, non-keratinizing type may be p16 positive and EBER negative (see below), especially in nodal metastasis from occult primary.
- No correlation between the size of the primary carcinoma, which may be only a few millimeters, and the neck metastasis, which may be large (several centimeters)

Nasopharyngeal Carcinoma, Nonkeratinizing Undifferentiated Type (Figs. 10-11 through 10-13)

- Represents approximately 60% of all NPC and is the most frequent tumor type seen in pediatric age groups
- Neoplastic cells are characterized by the presence of round nuclei, prominent eosinophilic nucleoli, dispersed nuclear chromatin, and scant eosinophilic to amphophilic cytoplasm.
- Keratinization is typically absent.
- Increased mitoses, including atypical forms, may be present.
- A prominent non-neoplastic lymphoid component composed of mature lymphocytes and plasma cells is seen in association with the malignant epithelial cellular infiltrate, although in any given example there may be a relative absence of an associated lymphoplasmacytic cell infiltrate:
 - Other inflammatory cell types that can be present include eosinophils and neutrophils, and scattered epithelioid granulomas may be present.
- May have a syncytial growth with cohesive or nested cells or has a diffuse cellular infiltrate composed of noncohesive cells:
 - Diffuse pattern is the one that is difficult to differentiate from a malignant lymphoma by light microscopy.
- Regaud and Schmincke patterns in nonkeratinizing carcinoma, undifferentiated type, refer to specific growth patterns, including:
 - Regaud pattern:
 - Cohesive (syncytial) nests and cords sharply distinct from surrounding lymphoid stroma
- Schmincke pattern:
 - Noncohesive cells (individual/single neoplastic cells or small tumor nests) infiltrated and potentially obscured by lymphoid infiltrate
 - These eponyms and their correlated growth have no bearing on the biology of the disease but may affect, especially with the Schmincke pattern, the diagnosis and differential diagnosis.
- Other uncommon cell types and/or growth patterns include:
 - Spindle-shaped neoplastic cells (Fig. 10-14)
 - Reticulated growth pattern (see Fig. 10-14)
- Infiltrative growth of this tumor generally does not produce a host desmoplastic response:
 - Absence of desmoplasia may be problematic in biopsy samples because the tumor may be overrun by the benign lymphoplasmacytic cell infiltrate and thus is easily overlooked.
 - Similarly, metastasis to cervical lymph nodes may not elicit a desmoplastic response in the involved lymph node.
- Because the distinction between the nonkeratinizing differentiated from the nonkeratinizing undifferentiated is of no clinical or prognostic significance, subclassification into differentiated and undifferentiated subtypes is optional:
 - Histologically, 26% of the NPC had features of more than one tumor type so that classification in such a situation is according to the dominant component.
 - Histologic distinction among the three types of NPCs may not always be clear, with overlapping histology in any given tumor.
- It is uncommon to identify the presence of a precursor lesion in the form of intraepithelial dysplasia or an in situ carcinoma:
 - If such a precursor lesion is present, the changes are similar to those of other upper aerodigestive tract sites and is characterized by the presence of a variably thickened epithelium with nuclear hyperchromasia, loss of cell polarity with nuclear crowding, increased nuclear-to-cytoplasmic ratio, prominent nucleoli, and increased mitotic activity:
 - These changes can be seen in the surface or crypt epithelium.
 - In most examples an invasive carcinoma is present without identification of surface epithelial dysplasia and/or carcinoma in situ; nevertheless, NPC originates from nasopharyngeal surface or crypt epithelium.
- Immunohistochemistry (for all three histologic types):
 - Strong immunoreactivity for cytokeratins, including AE1/AE3, CAM5.2, CK5/6, OSCAR, and EMA
 - p63 (nuclear) strongly and diffusely reactive
 - No immunoreactivity for hematolymphoid markers (positive in non-neoplastic lymphoplasmacytic infiltrate, including CD45, CD3, and CD20), melanocytic markers, myogenic markers

Fig. 10-11. Nasopharyngeal carcinoma, nonkeratinizing undifferentiated.

A, Infiltrating round to oval tumor nests surrounded by non-neoplastic lymphoid proliferation. Note the absence of a desmoplastic response to the invasive carcinoma. **B**, Syncytial neoplastic nests composed of cells with enlarged round to oval nuclei with vesicular chromatin, prominent eosinophilic nucleoli, and scant cytoplasm with indistinct cell margins; neoplastic cells are **(C)** cytokeratin positive, **(D)** p63 (nuclear) positive, and **(E)** EBER (nuclear) positive.

Fig. 10-12. Nasopharyngeal carcinoma, nonkeratinizing undifferentiated.

A and B (left panel), Diffuse, noncohesive cellular infiltrate composed of cells with oval or round vesicular nuclei, prominent eosinophilic nucleoli, scant cytoplasm, indistinct cell margins; the growth characteristics and cell types raise concern for a large cell B-cell lymphoma but **(B, right panel)** the neoplastic cells are cytokeratin positive with meshwork pattern of staining) confirming the diagnosis of carcinoma. **C,** Lesional cells are EBV positive (nuclear staining).

- Identification of EBV:
 - Immunohistochemistry:
 - Latent membrane protein 1 (LMP-1) reactivity:
 - Considered to lack sensitivity
 - In situ hybridization for Epstein-Barr encoded RNA (EBER):
 - Considered “gold standard”
 - Strong and diffuse nuclear staining
 - Invariably present in nonkeratinizing subtypes (i.e., differentiated, undifferentiated) but not true of the keratinizing subtype in which the detection of EBV genomes is variable and, if present, is generally limited to scattered dysplastic intraepithelial cells
- p16 immunoreactivity may be present in NPC (Fig. 10-15):
 - Morphologically similar to the EBV-associated carcinomas but will be negative for EBER and positive for p16
 - Cytogenetics and molecular genetics:
 - Consistent nonrandom deletions and rearrangement of the short arm of chromosome 3 found in NPC
 - Genetic instabilities (losses and gains) are common molecular events in NPC and play an important role in the development and progression of NPC:
 - Loss of heterozygosity (LOH) and comparative genomic hybridization (CGH) have shown high frequent allelic losses on chromosomes 1p, 3p, 9p, 9q, 11q, 13q, 14q, 16q, and 19q
 - CGH analysis has shown gains on chromosome 1q, 8q, 18q, and loss on 9p closely related to advanced stage of NPC
 - High frequent LOH on 3p in normal nasopharyngeal epithelium (74%) and dysplasia lesions (75%) from the southern Chinese have been found, suggesting that LOH at 3p may be an earlier genetic event of NPC tumorigenesis.

Fig. 10-13. Nasopharyngeal carcinoma, nonkeratinizing undifferentiated.

A, Owing to the absence of a host desmoplastic response to invasive carcinoma, at low magnification these findings appear to be those of a mixed inflammatory cell infiltrate with no suggestion that an invasive carcinoma is present. **B**, At higher magnification numerous neoplastic cells are seen but have the appearance of histiocytic cells as part of a mixed inflammatory cell infiltrate; scattered mitotic figures are present (*arrows*); the epithelial nature of the lesional cells are confirmed by the presence of (**C**) cytokeratin immunoreactivity showing a meshwork pattern of staining and (**D**) p63 (nuclear) staining. **E**, Strong association of the neoplasm with Epstein-Barr virus is confirmed by EBER positivity (nuclear staining).

Fig. 10-14. NPC, variant histology.

A and B, Nasopharyngeal carcinoma, undifferentiated with fascicular growth composed of spindle-shaped cells; an associated mixed inflammatory cell infiltrate is present. The spindle-shaped cells are **(C)** cytokeratin positive and **(D)** EBER positive (nuclear staining). **E**, Nasopharyngeal carcinoma, undifferentiated with reticulated growth; lesional cells are **(F)** cytokeratin positive and **(G)** EBER positive (nuclear staining). (Slides from reticulated growth pattern provided courtesy of Fredrik Petersson, MD.)

Fig. 10-15. Example of HPV-associated nasopharyngeal carcinoma.

A, Nasopharyngeal carcinoma characterized by the presence of a submucosal neoplastic infiltrate (*right side of image*). **B**, High magnification showing cytomorphic features of nonkeratinizing undifferentiated carcinoma; scattered mitoses are present (*arrows*). **C**, Lesional cells are immunoreactive for p16. EBER staining was negative (not shown).

- Development of NPC likely involves cumulative genetic and epigenetic changes in a background of predisposed genetic and environmental factors.
- Genome-wide studies have identified multiple chromosomal abnormalities with involvement of specific oncogenes and tumor suppressor genes, including inactivation of the p16 tumor suppressor gene on 9p21, the most common molecular alteration in NPC tumorigenesis.
- Alterations of genes such as Ras association domain family 1A (RASSF1A), p16/INK4A, p14/ARF suggest that multiple cellular pathways are dysregulated in the NPC cells.
- Findings on the precancerous lesions revealed early genetic changes and a critical role of EBV latent infection in the development of this cancer.

Differential Diagnosis

- Diagnosis of the keratinizing and nonkeratinizing types of NPC is usually straightforward.
- NPC, nonkeratinizing undifferentiated type, primarily when it occurs as a diffuse cellular infiltrate composed of dyscohesive cells, may be difficult to distinguish from non-Hodgkin malignant lymphoma ([Table 10-5](#)):
 - Differentiation is readily accomplished by immunohistochemical stains:
 - NPC will be reactive with cytokeratins and not negative for leukocyte common antigen (LCA).
 - Non-Hodgkin malignant lymphomas of the nasopharynx are predominantly of B-cell lineage and will be reactive with LCA and B-cell lineage markers (e.g., CD20, others).

TABLE 10-5 NPC, Nonkeratinizing Undifferentiated: Differential Diagnosis

Tumor	Gender/Age	Clinical	Histology	IHC	Treatment and Prognosis
NPC, UND	M > F; >6th decade	Airway obstruction; aural symptoms; neck mass	Cohesive vs dyscohesive; large cells with round nuclei, prominent eosinophilic nucleoli; increase mitotic activity	Epithelial markers +; EBV positive	Radioresponsive; 75% 5-year survival
SNUC	M > F; wide age range 3rd-9th decade with mean in 6th decade	Rapid onset (weeks to months); multiple symptoms include nasal obstruction, epistaxis, proptosis, visual disturbances (e.g., diplopia), facial pain, and symptoms of cranial nerve involvement	Overlapping histology with NPC, UND	Epithelial markers +; EBV negative	Not radioresponsive; poor prognosis often lethal over relatively short time periods
DLBCL	M > F; 5th-6th decade	Airway obstruction; aural symptoms; neck mass	Dyscohesive; diffuse growth; pleomorphic large cells and immunoblasts; large cells with round nuclei, prominent eosinophilic nucleoli; increased mitotic activity; necrosis	CD45, CD20, CD79a, PAX5, MUM1 positive; surface Ig (IGM>IgG>IgA) +	Multiagent chemotherapy and radiotherapy; prognosis is dependent on the clinical stage: overall 10-year disease-free survival (for all treatment modalities) is approximately 66%; overall survival rate of 82%; relapse occurs in from 30% to 45% of patients
MMM	M > F; 5th-6th decade	Airway obstruction; aural symptoms; pain; epistaxis	Varied growth including solid, organoid, alveolar and storiform; pleomorphic epithelioid and spindle cells; numerous mitoses	S100 protein, HMB-45, melan-A, tyrosinase, SOX10, vimentin positive	Surgery plus radiotherapy; overall poor prognosis
RMS	M = F; 1st-2nd decades but can be seen in adults	Airway obstruction; aural symptoms; pain	Various histologic types: embryonal, alveolar, pleomorphic; small round cells to large pleomorphic cells	Desmin, myoglobin, myogenin (myf-4) positive	Surgery, multiagent chemotherapy with or without radiotherapy Overall survival rates based on data from IRS-IV includes: 95% for low-risk patients; 75% for intermediate-risk patients; 27% for high-risk patients

DLBCL, Diffuse large B-cell lymphoma; MMM, mucosal malignant melanoma; NPC, UND, nasopharyngeal undifferentiated carcinoma; RMS, rhabdomyosarcoma; SNUC, sinonasal undifferentiated carcinoma.

- p63 is typically a marker of squamous cell lineage but may also be present in lymphomas.
- Sinonasal undifferentiated carcinoma (SNUC):
 - Overlapping histology especially with NPC, nonkeratinizing undifferentiated type
 - SNUCs are EBER negative.
 - Critically important to differentiate NPC from SNUC given the stark differences in treatment and prognosis between these tumor types:
- NPC: radioresponsive; good overall prognosis
- SNUC: not radioresponsive; poor prognosis often lethal over relatively short time periods
- HPV-associated HNSCC:
 - Overlapping histology with NPC, nonkeratinizing differentiated and undifferentiated types
 - EBV-associated HNSCC and HPV-associated NPC may present with cervical neck metastasis in the face of an occult primary neoplasm such

that differentiation cannot be made by light microscopic features and immunohistochemical staining for cytokeratins and p63; in this setting:

- Presence of EBV would support nasopharyngeal origin.
- Presence of HPV would support oropharyngeal origin.
- Other tumor types that might be included in the differential diagnosis include mucosal malignant melanoma and rhabdomyosarcoma:
 - Differentiation easily achieved by immunohistochemical staining:
 - Melanoma: S100 protein, HMB45, SOX10, MITF1, melan-A, tyrosinase positive; cytokeratins, EBER negative
 - Rhabdomyosarcoma: desmin, myogenin, myoglobin positive; cytokeratins, EBER negative; cytokeratins, EBER negative

Treatment and Prognosis

- As a result of the anatomic constraints imposed by the nasopharynx and the tendency of these neoplasms to present at an advanced stage, supervoltage radiotherapy (50 to 60 to 80 Gy) with or without adjuvant chemotherapy is considered the preferred treatment for all histologic subtypes:
 - Patients with early stage tumors (T1/T2) amenable to treatment with radiation therapy alone
 - Patients with T3/T4 lesions or significant nodal disease require more intensive treatments, including chemotherapy either sequentially concurrently or both with radiation therapy, as outcomes with radiation alone lead to higher rates of locoregional failure.
 - Surgical intervention reserved for patients who fail radiation therapy
- Technical advances in treatment planning systems incorporating CT have led to development of conformational therapies, including three-dimensional conformal therapy and intensity-modulated radiation therapy (IMRT):
 - Provides accurate delineation of tumor volumes and adjacent critical structures allowing for achieving maximal therapeutic benefit
 - Fusion with MRI or PET/CT crucial to accurately follow tumor spread three dimensionally
- Overall 5-year survival:
 - 20% to 40% for keratinizing squamous cell carcinoma.
 - Approximately 75% for nonkeratinizing carcinomas (differentiated and undifferentiated).
- TNM classification for NPC is detailed in [Table 10-6](#).

TABLE 10-6 TNM Classification: Pharyngeal Carcinoma

Primary Tumor (T)		Hypopharynx	
TX	Primary tumor cannot be assessed	T1	Tumor limited to one subsite of the hypopharynx and 2 cm or less in greatest dimension
T0	No evidence of primary tumor	T2	Tumor invades more than one subsite of the hypopharynx or an adjacent site, or measures more than 2 cm but not more than 4 cm in greatest dimension without fixation of the hemilarynx
Tis	Carcinoma in situ	T3	Tumor more than 4 cm in greatest dimension or with fixation of the hemilarynx or extension to esophagus
Nasopharynx		T4a	Moderately advanced local disease Tumor invades thyroid/cricoid cartilage, hyoid bone, thyroid gland, esophagus, or central compartment soft tissue [†]
T1	Tumor confined to nasopharynx, or tumor extends to oropharynx and/or nasal cavity without parapharyngeal extension*	T4b	Very advanced local disease Tumor invades prevertebral fascia, encases carotid artery, or involves mediastinal structures
T2	Tumor with parapharyngeal extension*	Regional Lymph Nodes (N)	
T3	Tumor involves bony structures of skull base and/or paranasal sinuses		
T4	Tumor with intracranial extension and/or involvement of cranial nerves, infratemporal fossa, hypopharynx, orbit, or masticator space	The distribution and the prognostic impact of regional lymph node spread from nasopharynx cancer, particularly of the undifferentiated type, are different from those of other head and neck mucosal cancers and justify the use of a different N classification scheme.	
Oropharynx			
T1	Tumor 2 cm or less in greatest dimension		
T2	Tumor more than 2 cm but not more than 4 cm in greatest dimension		
T3	Tumor more than 4 cm in greatest dimension or extension to lingual surface of epiglottis		
T4a	Moderately advanced local disease Tumor invades the larynx, deep extrinsic muscle of tongue, medial pterygoid, hard palate, or mandible [†]		
T4b	Very advanced local disease Tumor invades lateral pterygoid muscle, pterygoid plates, lateral nasopharynx, or skull base or encases carotid artery		

TABLE 10-6 TNM Classification: Pharyngeal Carcinoma—cont'd

Regional Lymph Nodes (N) ^f		Distant Metastasis (M)	
NX	Regional lymph nodes cannot be assessed	M0	No distant metastasis
N0	No regional lymph node metastasis	M1	Distant metastasis
N1	Unilateral metastasis in lymph node(s), 6 cm or less in greatest dimension, above the supraclavicular fossa, and/or unilateral or bilateral, retropharyngeal lymph nodes, 6 cm or less, in greatest dimension ^g	Anatomic Stage/Prognostic Indicators	
N2	Bilateral metastasis in cervical lymph node(s), 6 cm or less in greatest dimension, above the supraclavicular fossa ^g	Nasopharynx	
N3	Metastasis in a lymph node(s)* >6 cm and/or to the supraclavicular fossa ^g	Stage 0	
N3a	Greater than 6 cm in greatest dimension	Stage I	
N3b	Extension to the supraclavicular fossa ^h	Stage II	
		Stage III	
		Stage IVA	
		Stage IVB	
		Stage IVC	
		Oropharynx, Hypopharynx	
		Stage 0	
		Stage I	
		Stage II	
		Stage III	
		Stage IVA	
		Stage IVB	
		Stage IVC	

Used with permission from Edge et al: AJCC cancer staging manual, ed 7, New York, 2010, Springer-Verlag, 2010, pp 45-46.

*Parapharyngeal extension denotes posterolateral infiltration of tumor.

^fMucosal extension to lingual surface of epiglottis from primary tumors of the base of the tongue and vallecula does not constitute invasion of larynx.

^gCentral compartment soft tissue includes prelaryngeal strap muscles and subcutaneous fat.

^hMidline nodes are considered ipsilateral nodes.

ⁱSupraclavicular zone or fossa is relevant to the staging of nasopharyngeal carcinoma and is the triangular region originally described by Ho. It is defined by three points:

- (1) The superior margin of the sternal end of the clavicle
- (2) The superior margin of the lateral end of the clavicle
- (3) The point where the neck meets the shoulder

Note that this would include caudal portions of levels IV and VB. All cases with lymph nodes (whole or part) in the fossa are considered N3b.

^fMetastases at level VII are considered regional lymph node metastases.

- Clinical stage at presentation represents the most important prognostic factor:
 - 5-year disease-specific survival (DSS) for:
 - Stage I is 98%.
 - Stage IIA-B is 95%.
 - Stage III is 86%.
 - Stage IVA-B is 73%.
- Factors that may affect prognosis include the clinical stage, patient age and gender, presence of keratinization, lymph node metastasis, and possibly genetic factors:
 - Better prognosis is associated with early (lower) clinical stage, younger patient age, and nonkeratinizing histology.

- Worse prognosis is seen with higher stage tumors, older patients, and male gender, as well as patients with the HLA-Aw33-C3-B58/DR3 haplotype, whereas patients with A2-Cw11-Bw46/DR9 haplotype have longer survival.
- Children and adolescents tend to present at a more advanced clinical stage but still retain a relatively good rate of long-term survival but are prone to serious long-term treatment-related morbidities.
- Patients with the keratinizing type of NPC tend to have a higher incidence of locally advanced tumor but a lower incidence of lymphatic and/or distant spread:
 - Despite the above findings, patients with the keratinizing NPC had a poorer 5-year survival rate than those with the other histologic subtypes due to a higher incidence of deaths secondary to local uncontrollable disease and nodal metastases.
- NPC frequently metastasizes to regional lymph nodes and the presence of lymph node metastasis decreases survival by approximately 10% to 20%.
- A large percentage of NPC, particularly of the undifferentiated type, metastasize to sites below the clavicle, including the lungs, bone (ribs and spine), and liver.
- Patterns of spread include invasion into adjacent soft tissues, sinonasal tract, paranasal sinuses, posteriorly to the carotid sheath with involvement of cranial nerves IX, X, or XI, and skull base as well as spreading intracranially (Fig. 10-16):
 - Risk of developing a synchronous or metachronous second primary malignancy in patients with NPC is approximately 4%:
 - Incidence is lower than in other head and neck sites.
 - Quantitative real-time PCR test (qPCR) for circulating EBV DNA found to be useful in the clinical management of NPC patients:
 - EBV DNA qPCR has good sensitivity and specificity in the detection of NPC at disease onset.
 - Increased viral DNA load found in NPC patients at late stages of disease
 - High EBV DNA load at disease onset or detectable viral load post-treatment associated with poor survival or frequent relapse
 - Residual EBV DNA load after primary treatment could be a useful indicator to justify adjuvant chemotherapy.
 - qPCR test may also be applied to define a poor prognostic group in patients at early stage (I/II) for implementing concurrent chemo-radiotherapy (chemo-RT) to improve patients' outcome.
 - Also useful to monitor distant metastases or response to radiotherapy, chemo-RT, or surgery
 - EBV serologic biomarkers may enhance accuracy of TNM staging:
 - Serum VCA-IgA/EA-IgA titers and plasma EBV DNA correlated strongly with TNM classification:
 - VCA-IgA-positive rate significantly associated with advanced N classification and stage
 - EA-IgA-positive rate significantly associated with advanced T and N classifications and stage
 - EBV-DNA-positive rate significantly associated with advanced T, N, and M classifications and stage
 - Percentage of triple-positive patients higher in patients with advanced TNM classification
 - Plasma EBV DNA load could accurately predict metastatic disease.

Fig. 10-16. Patterns of spread in NPC.

Sagittal and axial schematic illustrations demonstrate the potential pathways of spread (arrows) for nasopharyngeal carcinomas. (From Mukherji SK, Pillsbury H, Castillo M: *Imaging squamous cell carcinomas of the upper aerodigestive tract: what the clinicians need to know*, Radiology 205:629-646, 1997.)

Basaloid Squamous Cell Carcinoma (BSCC) of the Nasopharynx

- Uncommon type of nasopharyngeal carcinoma
- Morphologically similar to BSCC of other (more common) head and neck sites
- Reported to show lower biologic aggressiveness as compared with BSCC of other head and neck sites
- Mixed reports identifying association with EBV:
 - Asian patients positive
 - Non-Asian patients negative
- Not associated with HPV unlike oropharyngeal BSCC; see later in this chapter.
- For more complete discussion see Section 5, Larynx.

Oropharyngeal Squamous Cell Carcinoma

- Oropharynx encompasses multiple different sites, including:
 - Soft palate and uvula
 - Palatine (faucial) tonsillar region, including tonsillar fossa encasing the palatine tonsils and pillars
 - Base of tongue extends inferiorly from circumvallate papillae to the vallecula (base of epiglottis)
 - Posterior and lateral oropharyngeal walls between the nasopharynx and pharyngoepiglottic fold
- Retromolar trigone is part of the oral cavity, and although carcinomas of the retromolar trigone often involve the oropharynx and behave like oropharyngeal cancers, it is discussed in Section 2, Oral Cavity.
- Hypopharyngeal carcinoma, including the piriform sinus, is often lumped with laryngeal carcinomas but will be discussed below under the general category of pharyngeal carcinomas.
- In the head and neck, HPV has emerged as a major pathogen associated with squamous cell carcinomas, in particular of the tonsil and base of tongue.
- Oropharyngeal squamous cell carcinomas other than those of the tonsil and base of tongue are associated with tobacco and alcohol use/abuse.
- Oropharyngeal squamous cell carcinoma can be classified into morphologic subtypes, including:
 - Nonkeratinizing type:
 - Very strong association with HPV (HPV-associated SCC)
 - Most common

- Typically invades without associated desmoplasia
- Nonkeratinizing with squamous differentiation (maturation or hybrid carcinoma):
 - Intermediate association with HPV but considered closely related to the nonkeratinizing type
- Keratinizing type (“conventional” SCC):
 - Weak to no association with HPV (non-HPV-associated SCC)
- TNM classification for oropharyngeal carcinoma is detailed in Table 10-6.

HPV-Associated Squamous Cell Carcinoma of the Tonsil and Base of Tongue

Definition: Squamous cell carcinoma predominantly but not exclusively nonkeratinizing with basaloid cell morphology that is strongly associated with HPV-16 with overall better outcome than non-HPV associated HNSCCs (Table 10-7).

Synonyms: Nonkeratinizing squamous cell carcinoma; basaloid carcinoma; basal-like carcinoma; poorly differentiated carcinoma

NOTE:

- Initial designation for these cancers as basaloid may result in confusion with basaloid SCC, which is a high-grade variant of conventional SCC predilecting to the hypopharynx (i.e., piriform sinus) and supraglottic larynx not typically associated with HPV (or EBV); see Section 6, Larynx
- HPV-associated squamous cell carcinomas originating from tonsillar crypt epithelium may be viewed and diagnosed as “poorly differentiated”

TABLE 10-7 Comparison Between HPV-Positive and HPV-Negative SCC

	HPV-Positive SCC	HPV-Negative SCC
Age	Younger	Older
Gender	M = F	M > F
Race	Caucasian >>>> African American	Caucasian = African American
Risk factors (Tobacco/alcohol)	No known risk factors (usually nonsmokers, nondrinkers)	Associated with tobacco and/or alcohol use/abuse
Primary location	Oropharynx (base of tongue; tonsil)	All mucosal sites of the UADT
Histology	Nonkeratinizing carcinoma predominantly composed of basaloid cells	Keratinizing squamous cell carcinoma
p16	Positive	Negative
Prognosis	Better disease-free and overall survival	Worse disease-free and overall survival
Tumor stage at presentation	Often higher (more nodal metastasis)	Often lower

HPV, Human papillomavirus; SCC, squamous cell carcinoma; UADT, upper aerodigestive tract.

given the immature appearance of the lesional cells as well as the absence of differentiation in the form of keratinization and intercellular bridges; however, such cancers are in fact differentiated, originating and recapitulating the features of its cell of origin—that of the specialized tonsillar crypt reticulated epithelium.

Clinical

- Approximately 20% to 25% of squamous cell carcinomas of the upper aerodigestive tract are related to HPV infection:
 - Incidence of HPV-associated HNSCC is rising:
 - Increase in the prevalence of HPV-associated oropharyngeal squamous cell carcinoma from:
 - 21% in the pre-1990 time period
 - To 51% in 1990 to 1999
 - To 65% for 2000 to present
 - In contrast, incidence of HPV-unrelated HNSCC has stabilized or is decreasing with the decreasing use of tobacco products.
- Majority of HPV-associated SCC of the upper aerodigestive occurs in the oropharynx predominantly arising at the base of the tongue or palatine tonsil:
 - Propensity for HPV to infect the base of tongue and tonsil may be due to greater accessibility of the virus to the basal and proliferating squamous cells in these locations possibly secondary to epithelial disruption
- HPV-associated oropharyngeal SCC represents a unique subtype of HNSCC characterized by (see [Table 10-7](#)):
 - Absence (usually but not always) of known risk factors for HNSCC (i.e., nonsmokers and nondrinkers)
 - Patients who are younger patients than those with non-HPV-associated HNSCC
 - Better outcome (better overall and disease-specific survival) than non-HPV-associated HNSCCs
 - Their tendency to be highly curable even in presence of advanced disease
- Lower prevalence of HPV reported in African-American populations:
 - Largely accounts for poorer survival in African-American populations from oropharyngeal cancer but not other HNSCC
- Symptoms associated with HPV-associated oropharyngeal SCC:
 - Often relate to a mass; however, these cancers may be small and clinically/radiographically difficult to detect
 - Frequently develop early neck metastasis and may present as metastatic cancer to a cervical neck lymph node from an unknown primary site:
 - There is no correlation between the size of the primary carcinoma and the size of the metastatic carcinoma; a primary carcinoma may be tiny/small, measuring only a few millimeters but give rise to a large metastasis measuring several centimeters.
 - Similar lack of size correlation between the primary carcinoma and its metastasis seen in association to nasopharyngeal nonkeratinizing carcinomas
- Common presenting symptoms for tonsillar carcinomas may include:
 - Ipsilateral referred otalgia, odynophagia, sensation of a lump or foreign body in the throat
- Base of tongue carcinomas tend to be highly insidious:
 - Base of tongue is almost devoid of pain fibers.
 - Such carcinomas are frequently asymptomatic, presenting with higher clinical stage disease.
 - Such carcinomas often present with neck node metastases only to have base of tongue lesion found on full evaluation.
 - Visualization of this area on physical examination can be difficult and lesions may be missed.
 - Referred otalgia may represent the first symptoms.
 - Patients may experience sensation of a mass or discomfort in the throat, bleeding, difficulty with speech and swallowing, and pain in later stages.
- Radiology ([Figs. 10-17 to 10-19](#)):
 - PET/CT scan:
 - Plays an important role in the imaging evaluation of these cancers, in particular in trying to localize/identify the primary oropharyngeal carcinoma.
 - Combination of the two modalities has highest yield in discovering the primary head and neck cancer
 - PET/CT superior to either PET or CT alone
 - Metabolic imaging:
 - Neoplasms have increased metabolic activity with respect to surrounding normal mucosa:
 - Isotope ^{18}F -fluorodeoxyglucose (FDG), a glucose analog, enters cells using normal transport mechanisms.
 - The application of FDG uses the fact that glucose metabolism (i.e., FDG uptake) is increased in malignant cells but cannot be further metabolized, remaining in the tumor tissues.
 - Imaging modalities using FDG include positron emission tomography (PET) (FDG-PET):
 - ◻ Increases the detection of primary cancer site by up to 54%

Fig. 10-17. Radiologic imaging in tonsillar carcinoma.

A, Axial T2-weighted image through an exophytic right tonsillar fossa SCC (*arrow*) with bilateral cervical metastases (*N*). **B**, Axial image slightly cranial to **A**, demonstrating subtle marrow involvement (*curved arrow*) and right lateral retropharyngeal lymph node disease. **C**, Sagittal precontrast T1-weighted image demonstrates extension to the soft palate (*arrowheads*). (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 29-15, p 1761.)

Pathology

Nonkeratinizing Carcinoma

Cytomorphology (see Section 4, Fig. 13-39)

- Cohesive and dyscohesive clusters or groups of malignant epithelial cells with basaloid cytomorphology, including:
 - Hyperchromatic nuclei with coarse nuclear chromatin, nuclear pleomorphism
 - Increased nuclear-to-cytoplasmic ratio

- Increased mitotic activity, including atypical mitoses
- Necrosis (individual cell and confluent areas) may be present.
- Typically, absence of keratinization, although focal keratinization may be present

NOTE: Given their basaloid morphology, including features of a histologic higher-grade carcinoma, such carcinomas (whether on fine-needle aspiration or biopsy) have been erroneously designated as poorly

Fig. 10-18. PET/CT scan in tonsillar carcinoma.

A, Axial pretreatment PET/CT demonstrates a large right tonsillar carcinoma (*curved arrow*) that extended across the tongue base to involve the left tonsil (*wavy arrow*). Note the metastatic right level II node (*arrowhead*). **B**, Following chemoradiation, there is a marked reduction in the right tonsillar size. The pharyngeal mucosa, although prominent, is symmetric. The right level II node (*arrowhead*) has a low-attenuation center, consistent with necrosis. No FDG activity is present. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 29-23, p 1765.)

differentiated. In fact, these nonkeratinizing carcinomas are considered better differentiated carcinomas, recapitulating the crypt epithelium from which they may arise.

Gross

- No specific macroscopic findings:
 - Often clinical presentation is with cervical lymph node metastasis without known primary carcinoma.
 - Identification of primary carcinoma may occur in biopsy material without macroscopic evidence of a lesion.
- Carcinomas of anterior tonsillar pillar can be erythroplakic and/or exophytic.
- Carcinomas of tonsillar fossa in contrast to tonsillar pillar tend to be either exophytic or ulcerative.

Histology (Figs. 10-20 and 10-21)

- Arise from tonsillar crypts located within the depth of the tonsil (palatine or lingual):

- Involvement of surface epithelium not commonly present
- When there is involvement of surface epithelium, it usually occurs by contiguous extension from the crypts.
- Transition from surface epithelial intraepithelial dysplasia to invasive carcinoma that typifies most of the squamous cell carcinomas of mucosal sites of the upper aerodigestive tract is not typically evident in HPV-associated carcinoma.
- Invasive growth may include solid sheets, trabeculae, cords, and nests, but individual infiltrative cells can be seen:
 - Often are cystic with central areas of necrosis and frequently metastasize as cystic metastatic carcinomas (see Section 5, The Neck):
 - In the absence of a known primary carcinoma, such cystic neck masses may be considered branchial cleft cysts with malignant transformation, a diagnosis of questionable existence.

Fig. 10-19. Radiologic imaging in base of tongue carcinoma.

A, Sagittal T1-weighted image with prominent mass at the base of the tongue (*arrow*). **B**, Mass involves the entire tongue base, right to left (*arrows*) on T2-weighted image, with extension into the left-sided deep tongue musculature (*arrowhead*). **C**, Axial, contrast-enhanced CT scan shows an asymmetric soft-tissue fullness in the right base of the tongue. This asymmetry should raise concern. This was a SCC of the base of the tongue. **D**, Sagittal, T1-weighted MR image shows a large noninfiltrating mass in the base of the tongue. The mass is nonhomogeneous. This patient had a goiter of a lingual tonsil. This is an example of a nonmalignant mass in the base of the tongue. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 29-20, p 1763.)

Fig. 10-20. Histology of oropharyngeal HPV-associated SCC.

Oropharyngeal (tonsillar) HPV-associated nonkeratinizing squamous cell carcinoma characterized by the presence of (A) submucosal invasive neoplasm including solid nests as well as nests with cystic change and central areas of necrosis; (B) the overlying surface squamous epithelium is intact and uninvolved by the invasive carcinoma. An inflammatory cell infiltrate is present in and around the carcinoma but there is an absence of associated desmoplastic stromal response to the invasive carcinoma. C and D, The neoplastic cells whether in the solid foci or in the cystic foci are characterized by a basaloid cell morphology, including nuclear pleomorphism with increased mitotic activity and absence of keratinization. However, in other examples focal keratinization may be present but typically the extent of keratinization is limited. E, The epithelial nature of the lesion is confirmed by the presence of cytokeratin (AE1/AE3) immunoreactivity and (F) diffuse p63 (nuclear) staining.

Fig. 10-20, cont'd

G, Lesional cells are diffusely and strongly positive for p16 (nuclear and cytoplasmic staining).

- Invasive growth often without associated desmoplasia that typifies most other invasive carcinomas (with the exception of nasopharyngeal nonkeratinizing carcinomas).
- Typical histologic features are those of a nonkeratinizing carcinomas characterized by basaloid cell morphology:
 - Neoplastic cells include marked nuclear pleomorphism with increased mitotic activity, including atypical mitoses.
 - Focal keratinization may present:
 - Typically the extent of keratinization is limited, with the majority of the neoplastic cells lacking evidence of keratinization.
 - Not more than 10% maturing squamous differentiation
 - Often associated with a dense benign lymphocytic cell infiltrate (tumor infiltrating lymphocytes [TIL]):
 - Given the propensity for this carcinoma to invade without associated desmoplasia, the associated dense lymphocytic cell infiltrate may obscure the presence of the malignant cells.
 - Cytokeratin and p16 staining are invaluable in evaluating for the presence of invasive carcinoma.
 - May include papillary growth or may show growth and cytomorphic characteristics similar to nasopharyngeal nonkeratinizing carcinoma, undifferentiated type, including syncytial growth and cells with enlarged vesicular nuclei and prominent nucleoli:
 - Although this morphology overlaps with the EBV-associated nasopharyngeal carcinomas, this subset of oropharyngeal carcinomas is associated with HPV rather than EBV.
- Carcinoma in situ versus invasive carcinoma (Fig. 10-22):
 - Determining whether an HPV-associated carcinoma represents carcinoma in situ or invasive carcinoma can be problematic due to:
 - Origin from tonsillar crypt reticulated epithelium, which is penetrated by lymphocytes, thereby blurring the junction between the epithelium and the lymphoid stroma
 - Porous nature of the epithelial-to-lymphoid junction, where the basal cell layer is incomplete as well as the disruption and noncontinuous nature of its basement membrane
 - Absence of associated desmoplasia
 - In addition, very small foci of HPV-associated SCC may metastasize to regional lymph nodes in the absence of definitive evidence of invasion.
 - Given the challenges in any given case to determine if a focus of HPV-associated carcinoma is or is not invasive yet nodal metastasis may be present, a prudent approach would include regarding all such foci to be malignant and invasive even in the absence of unequivocal evidence of invasion.
- Large pleomorphic cells (tumor cell anaplasia) and multinucleation may be present, which has correlated to poorer clinical outcomes (Fig. 10-23).

Nonkeratinizing Carcinoma with Squamous Differentiation (Maturation or Hybrid Type) (Fig. 10-24)

- Oropharyngeal carcinoma with histologic features of keratinizing and nonkeratinizing squamous cell carcinomas:
 - Histology composed of predominantly classic nonkeratinizing carcinoma with a component of squamous differentiation, the latter identified in more than 10% of the overall surface area of maturing squamous differentiation:
 - Basaloid cells show a trend toward differentiation to a keratinizing phenotype at the periphery of the cell nests and trabeculae.
 - Strong association with HPV but the virus is slightly less frequently detected than in the oropharyngeal nonkeratinizing carcinoma
 - Immunohistochemistry for HPV-associated SCC:
 - Neoplastic cells express cytokeratins, including AE1/AE3, CAM5.2, and CK5/6, as well as p63 (diffuse and strong nuclear staining):
 - Extremely helpful in identifying the malignant cells in the presence of obscuring benign lymphoid infiltrate
 - p16 positive:
 - Surrogate marker for HPV16 (i.e., presence of p16 immunostaining correlates to the presence of HPV16)

Fig. 10-21. Biopsy of base of tongue HPV-associated SCC.

Base of tongue biopsy in a patient with cervical lymph node metastatic carcinoma diagnosed by fine-needle aspiration as poorly differentiated carcinoma. **A**, At low magnification a fragment of squamous mucosa with submucosal dense lymphoid infiltrate is present. At this magnification there is no suggestion that an invasive carcinoma is present in the form of readily identifiable infiltrative tumor nests (see Fig. 10-20 in comparison) and/or the presence of identifiable stromal desmoplasia. However, an invasive carcinoma is present along the deep edge of the specimen (*arrow*). **B** and **C**, At higher magnification, the invasive carcinoma becomes more evident as seen by a small cohesive cluster of malignant cells including focal keratinization (*arrow*) but also as individual tumor cells (between arrowheads) overrun and obscured by the lymphoid infiltrate. **C**, Higher magnification shows the individual malignant cells with basaloid nuclei. **D**, In deeper levels performed for immunohistochemical staining, a greater amount of carcinoma becomes evident by the strong cytokeratin (CAM5.2) immunoreactivity. **E**, Lesional cells are diffusely and strongly positive for p16 (nuclear and cytoplasmic staining). In spite of the very small focus of the primary base of tongue carcinoma (that parenthetically can be quite difficult to detect by clinical and radiologic evaluation), nodal metastatic disease can be large (several centimeters).

Fig. 10-22. In-situ versus invasive oropharyngeal HPV-associated SCC.

A and **B**, Areas in a tonsillar biopsy showing what appears to be carcinoma in situ (CIS) with the neoplastic basaloid cells apparently confined to crypt epithelium without evidence of invasion. **C**, Lesional cells are diffusely and strongly positive for p16 (nuclear and cytoplasmic staining). Determining whether an HPV-associated carcinoma represents carcinoma in situ or invasive carcinoma is problematic. Given the challenges in any given case to determine if a focus of HPV-associated carcinoma is or is not invasive, a prudent approach would include regarding all such foci to be malignant and invasive even in the absence of unequivocal evidence of invasion. Reasons for this approach include the facts that origin from tonsillar crypt reticulated epithelium penetrated by lymphocytes results in the blurring of the junction between the epithelium and the lymphoid stroma; the porous nature of the epithelial-to-lymphoid junction where the basal cell layer is incomplete as well as the disruption and noncontinuous nature of its basement membrane; very small foci of HPV-associated SCC including foci depicted in this image may metastasize to regional lymph nodes in the absence of definitive evidence of invasion.

- Reactivity pattern includes nuclear and cytoplasmic staining and is usually diffuse and strongly reactive; should be positive in $\geq 75\%$ of lesional cells.
- Considered a reliable predictor of a carcinoma originating from the oropharynx
- Can be performed on aspiration material and on tissue sampling
- High proliferation rate as seen by Ki67 (MIB1) staining
- EBER negative
- S100 protein negative
- No immunoreactivity for hematolymphoid markers and melanoma-specific markers
- Detection methods for HPV16 include:
 - Immunohistochemical (IHC) staining for p16, a surrogate marker for HPV16
 - HPV specific molecular tests:
 - DNA in situ hybridization (ISH)
 - mRNA techniques for identification of transcripts of viral oncogenes E6/E7 (at present considered gold-standard test to determine oncogenic role of HPV in a given tumor)

Fig. 10-23. Tumor cell anaplasia in oropharyngeal HPV-associated SCC.

Tonsillar HPV-associated nonkeratinizing squamous cell carcinoma with (A) large pleomorphic cells and (B) multinucleation may be present and have been reported to correlate to poorer clinical outcomes.

Fig. 10-24. Hybrid type of oropharyngeal HPV-associated SCC.

Oropharyngeal nonkeratinizing carcinoma with squamous differentiation (maturation or hybrid type) showing histologic features of both keratinizing and nonkeratinizing squamous cell carcinomas. A and B, Histologic features include foci of classic nonkeratinizing carcinoma (arrows) with a component of mature squamous differentiation (arrowheads), the latter identified in more than 10% of the overall surface area of maturing squamous differentiation. C, Strong association with HPV as evidenced by the presence of p16 immunoreactivity. Molecular analysis confirmed the presence of HPV (not shown).

- PCR-based (consensus and type-specific; real-time assays to quantify viral load)
- Some authorities advocate a combined approach to include IHC and ISH.
- p16 as a stand-alone test has validity based on:
 - Overexpression is very sensitive for the presence of transcriptionally active HPV (i.e., high correlation with detectable HPV RNA) with moderate to high specificity:
 - Approximately 10% of p16 positive tumors are HPV DNA negative due to either misclassification as HPV DNA negative because of insufficient sensitivity of the HPV DNA test or cases represent tumors in which p16 overexpression triggered by other cellular signaling pathways
 - Correlates strongly with patient outcomes (i.e., strong risk stratification for patient survival)
 - In addition, p16 IHC staining is:
 - Widely available
 - Easy to interpret
 - Focal/weak p16 staining should be confirmed by molecular testing
- Some authorities advocate a combined approach to include p16IHC with additional molecular testing especially in oropharyngeal cancers:
 - That are p16 negative but show classic HPV-associated histomorphology
 - That are p16 focal and weakly positive in presence of classic HPV-associated histomorphology
 - That are p16 positive oropharyngeal cancers without classic histomorphology
 - For enrollment/selection for clinical (therapeutic) protocols requiring confirmation of transcriptionally active virus
- Guidelines for p16 and/or HPV testing in head and neck carcinomas may include:
 - In an oropharyngeal biopsy showing atypical basaloid cells, the presence of p16 confirms the diagnosis of HPV-associated HNSCC.
 - In tumors with overlapping morphology, presence of p16 helps confirm the diagnosis of HPV-associated HNSCC.
 - In the presence of cervical nodal metastatic disease of unknown primary origin, p16 staining would:
 - Confirm the diagnosis of metastatic cystic SCC
 - Localize the primary site of origin to the oropharynx
 - Establish tumor classification, which then would reflex to specific treatment protocols
- Hybrid Capture 2 and Cervista reported to be as sensitive as PCR with fewer false positives than p16 immunohistochemical staining

Conventional Keratinizing Squamous Cell Carcinoma

- Oropharyngeal carcinoma typically composed of infiltrative nests with prominent stromal desmoplasia:
 - Characterized by polygonal cells with distinct cell borders, abundant eosinophilic cytoplasm
 - Squamous maturation in the form of keratin pearl formation, individual cell keratinization, and intercellular bridges
 - Squamous maturation is diffusely seen even in poorly differentiated carcinomas.
 - Typically not associated with HPV and are usually p16 negative.

Differential Diagnosis for Nonkeratinizing Carcinoma

- Basaloid squamous cell carcinoma (BSCC):
 - Non-HPV-associated BSCC has aggressive clinical behavior
 - Overlapping growth patterns and cell type between non-HPV-associated BSCC and HPV-associated carcinoma make differentiation between these two similar-appearing but biologically distinct cancers problematic.
 - Presence or absence of HPV represents the key feature in distinguishing these two tumor types.

Treatment and Prognosis

- Currently, there is no single standardized treatment strategy for HPV-associated HNSCC, and treatment regimens may include:
 - Radiation therapy alone
 - Combination of radiotherapy and chemotherapy (given concurrently or an induction therapy)
 - Surgery with or without adjuvant radiotherapy:
 - Surgical options include minimally invasive approaches, obviating the need for mandibulotomy, including transoral robotic surgery (TORS).
 - As compared with traditional open surgical techniques, TORS may:
 - Achieve complete surgical resection with associated reduced morbidity
 - Be associated with better quality of life
 - Further, TORS may improve functional outcomes when compared with nonsurgical treatment with radiation with or without chemotherapy.
- Patterns of spread for tonsillar carcinoma (Fig. 10-25):
 - Anterior tonsillar pillar carcinomas may spread:
 - Laterally to buccal mucosa
 - Along the superior constrictor muscle to the pterygomandibular raphe and from there to the buccinator muscle and retromolar trigone

Fig. 10-25. Patterns of spread for tonsillar carcinoma.

Sagittal and axial illustrations demonstrate the potential spread patterns of a tonsillar carcinoma (arrows). (From Mukherji SK, Pillsbury H, Castillo M: *Imaging squamous cell carcinomas of the upper aerodigestive tract: what the clinicians need to know*, Radiology 205:629-646, 1997.)

- Inferiorly base of tongue invasion may likely occur as a result of growth along the palatoglossus muscle.
- Superior extension can involve the hard palate.
- Medial extension may involve the oral tongue.
- Close proximity to mandible increased risk for periosteal and bone involvement
- Posterior and superior extension can lead to involvement of the pterygoid muscles with subsequent trismus and pain.
- Tonsillar fossa carcinomas may have patterns of spread similar to those of the anterior tonsillar pillar but may also include:
 - Lateral extension to parapharyngeal space toward the base of skull, causing neurologic signs and symptoms
 - Carcinomas of the posterior tonsillar pillar can extend inferiorly and involve the pharyngoepiglottic fold and posterior aspect of the thyroid cartilage.
- Patterns of spread for base of tongue carcinoma may include (Fig. 10-26):
 - Inferior spread to involve the vallecula, epiglottis, and preepiglottic fat:
 - More advanced cancers may extend to the hypopharynx and larynx.
 - Lateral and superior spread to involve the tonsil and pharyngeal mucosa:
 - Deeper extension can occur along the pterygo-mandibular raphe toward the mandible.
 - Lateral and posterior spread can also occur into parapharyngeal space and carotid sheath.

Fig. 10-26. Patterns of spread for tongue base carcinoma.

Sagittal and axial illustrations demonstrate the potential spread patterns of a tongue base carcinoma (arrows). (From Mukherji SK, Pillsbury H, Castillo M: *Imaging squamous cell carcinomas of the upper aerodigestive tract: what the clinicians need to know*, Radiology 205:629-646, 1997.)

- Anterior spread to floor of mouth and oral tongue
- Local advanced cancers can infiltrate deep muscle and cause fixation.
- As compared with non-HPV-associated HNSCC, HPV-associated HNSCC is:
 - Associated with a better outcome (better overall and disease-specific survival)
 - Highly curable even in presence of advanced clinical stage disease
- Factors that may be in play relative to their better outcome include the possibility of absence of field cancerization and presence of enhanced radiation sensitivity.
- Factors affecting prognosis include:
 - Positive prognostic benefit of HPV in HNSCC mitigated by negative prognostic effects of smoking
 - Increasing evidence TP53 mutation and high EGFR expression can increase resistance of HPV-associated carcinoma to therapy.
 - Current therapies associated with excess morbidities, including long-term swallowing dysfunction, reduced saliva production, and dysgeusia
 - Second primary malignancies may be less common in patients with HPV-associated tumors than HPV-negative tumors.
 - Rates of death from second primary cancers in HPV-associated HNSCC similar to rates associated with HPV-negative HNSCC
- HPV vaccines are expected to protect against most HPV-induced cancers:

- Primarily directed against development of cervical cancer
- Effects of HPV vaccine on incidence of HPV-associated HNSCC yet to be determined and with ongoing trials will be determined over time
- Targeted therapy:
 - Potential use of targeted therapy based on genomic findings including somatic mutations currently subject of clinical trials and potentially could be used in treatment of these cancers

HPV-Associated Basaloid Squamous Cell Carcinoma of the Oropharynx

- Histologically similar to basaloid squamous cell carcinoma arising in other mucosal sites of the upper aerodigestive tract; for more details including images see Section 5, Larynx.
- In contrast to non-oropharyngeal basaloid squamous cell carcinoma, many but not all of the oropharyngeal basaloid squamous cell carcinomas are associated with HPV16 (p16 positive).
- Overlapping growth patterns and cell types between non-HPV-associated basaloid squamous cell carcinoma and HPV-associated basaloid squamous cell carcinoma make differentiation between these two similar-appearing but biologically distinct cancers problematic.
 - Presence or absence of HPV represents the key feature in distinguishing these two tumor types.
- HPV-associated basaloid squamous cell carcinoma of the oropharynx:
 - Predilects to the base of tongue > tonsil
 - More common in men than women
 - Are immunoreactive for p16
 - Confers a better prognosis than non-HPV-associated basaloid squamous cell carcinoma

Nonkeratinizing (Lymphoepithelial-Like) Undifferentiated Carcinoma of the Oropharynx (Fig. 10-27)

- Represents a rare variant of nonkeratinizing carcinoma
- More than 90% occur in tonsils and base of tongue.
- Symptoms may include oropharyngeal mass and/or neck mass:
 - Cervical lymph node involvement occurs in approximately 70% of cases at presentation.
- Histomorphologic features similar to nasopharyngeal carcinoma, nonkeratinizing undifferentiated (see previously in this chapter)

- Immunohistochemistry:
 - Cytokeratins positive
 - Hematolymphoid markers negative
 - p16 positive
 - EBER negative
- Radiosensitive cancers:
 - Local failure: 3%
 - Regional failure: 5%
 - Distant failure: 19%

Conventional Keratinizing (Non-Viral-Associated) Squamous Cell Carcinoma of the Pharynx

- Incidence stabilized or decreasing with the decreasing use of tobacco products
- Clinical findings differ per site of occurrence (see below).
- Histology similar regardless of site of occurrence

Squamous Cell Carcinoma of the Soft Palate and Uvula

Anatomic Considerations

- Soft palate includes the uvula and incompletely separates the oral cavity and oropharynx from the nasopharynx:
 - Continuous laterally with the tonsillar pillars and attaches anteriorly to the hard palate
 - Forms the roof of the oropharynx and floor of the nasopharynx
 - Demarcates the oral cavity from the oropharynx as well as the oropharynx from the nasopharynx

Clinical

- More common in men than women; most frequently occurs in the fifth through eighth decades of life
- Symptoms include sore throat, sensation of a lump or foreign body in the throat, dysphagia, bleeding, trismus, and referred pain (e.g., otalgia):
 - Referred otalgia can be one of the first symptoms a patient experiences with a mass of the oropharynx
 - Mediated by cranial nerves IX and X
- Carcinomas of the soft palate almost exclusively found on the oropharyngeal rather than nasopharyngeal surface and may be localized at presentation or spread to adjacent structures, including tonsillar pillars and base of tongue:
 - Occasionally may extend laterally and superiorly as far as the nasopharynx

Fig. 10-27. Nonkeratinizing (lymphoepithelial-like) undifferentiated carcinoma of the oropharynx.

A and B, Histomorphologic features are similar to those of nasopharyngeal carcinoma, nonkeratinizing undifferentiated type, including syncytial growth composed of neoplastic cells with enlarged pleomorphic and vesicular nuclei and prominent nucleoli. **C,** Lesional cells are cytokeratin positive. In addition to localization to the base of tongue, **(D)** the lesional cells are p16 positive. EBER staining was negative (not shown). Molecular analysis confirmed the presence of HPV (not shown). This carcinoma can metastasize to cervical neck lymph nodes as an occult primary carcinoma. In such a scenario, purely based on the light microscopic features, a primary nasopharyngeal carcinoma would be the most likely consideration. EBER staining would be negative, and unless consideration was given for a possible oropharyngeal origin, p16 staining, which would be diagnostic, may not be performed.

- Involvement of the palatine nerve can result in carcinoma tracking along this pathway with extension to the base of the skull.
- Lymphatic involvement primarily to level II
- Carcinoma of the midline or uvula can result in bilateral neck metastases
- Retropharyngeal nodes are at risk
- Causes include primarily tobacco and alcohol use/abuse; other risk factors include:
 - Diet poor in fruits and vegetables
 - Chewing betel quid

Pathology Histology

- Originates from surface epithelium
 - Conventional keratinizing squamous cell carcinoma is the most common histologic type.
- Conventional invasive keratinizing squamous cell carcinoma is the most common histologic type:
 - Originates from surface epithelium, so intraepithelial dysplasia is often present and identifiable in the absence of ulceration.

- May be well, moderately, or poorly differentiated
- Desmoplastic stromal response present
- Histologic variants of squamous cell carcinoma may occur.

Treatment and Prognosis

- TNM classification for pharyngeal carcinoma is detailed in [Table 10-6](#).
- Treatment options for early stage disease (T1, T2) include:
 - Primary radiotherapy:
 - Increasing use of intensity-modulated radiotherapy (IMRT) with addition of image-guided radiotherapy (IGRT) has led to high rates of locoregional control with low incidence of long-term functional morbidity.
 - Primary surgery:
 - Primary surgery involves transoral laser microsurgery (TLM) or transoral robotic surgery (TORS) for the primary site and must be combined with a separate procedure to remove neck nodes:
 - Must be combined with (separate) procedure to remove neck nodes
 - May not be the only treatment needed and may require additional treatment with radiotherapy or concomitant chemotherapy-radiotherapy, depending on the pathologic findings in the primary tumor and the neck (e.g., lymph-vascular invasion, neurotropism, extranodal extension)
 - Surgery does not address the retropharyngeal nodes, which is an area at risk.
- Outcomes for early stage disease:
 - Primary RT:
 - 5-year initial and ultimate (after successful salvage) local control rates for stage I 84% and 89%, respectively
 - 5-year initial and ultimate (after successful salvage) local control rates for stage II 85% and 88%, respectively
 - 90% locoregional control rates for T1 and T2
 - 5-year disease-specific survival for stages I and II of 89% and 87%, respectively
 - 90% 5-year nodal control rate for N0 disease
 - 5-year freedom from distant metastases rate of 95% for stage I and 97% for stage II
 - Primary surgery:
 - 5-year disease-specific survival for stages I and II 70% and 53%, respectively
 - 5-year local control for stages I and II 83% and 74%, respectively
 - 5-year distant control for stages I and II 96% and 81%, respectively
 - 5-year disease-specific survival for stages I and II 87% and 66%, respectively
- Treatment options for advanced stage disease (T3, T4) includes:
 - Combined therapy options are preferred:
 - Concomitant chemotherapy and radiation therapy preferred management for most patient with stages III and IVA/B disease
 - Stage III disease:
 - Radiation therapy alone considered for certain patients with low bulk stage III lesions (i.e., T1-2N1M)
 - Primary surgery alone may be used for select patients with low bulk stage III disease
 - If there are negative margins on primary site surgery and negative neck specimens, surgery alone may be adequate.
 - Stage III patients with positive margins, positive nodes, or other adverse findings (neurotropism, lymph-vascular invasion) trigger postoperative radiotherapy or concomitant chemotherapy-radiotherapy especially if margins are positive or there is extranodal extension.
 - Stage IVA/B disease:
 - Concomitant chemotherapy and radiation therapy (i.e., cisplatin and IMRT) are the mainstays of treatment.
 - Stage IVC:
 - Determined by the extent of locoregional disease, resectability presence and extent of distant metastases, and performance status of the patient
- Outcomes for advanced stage disease:
 - 5-year outcomes for patients receiving primary surgery, surgery plus postoperative radiotherapy, or primary radiotherapy with or without chemotherapy include:
 - Local control for stages III and IV of 88% and 54%, respectively
 - Regional control local control for stages III and IV of 77% and 73%, respectively
 - Distant control for stages III and IV of 72% and 83%, respectively
 - Disease-free survival for stages III and IV of 54% and 36%, respectively
 - Overall survival for stages III and IV of 55% and 37%, respectively
 - Disease-specific survival for stages III and IV of 65% and 55%, respectively

Fig. 10-28. Patterns of spread for soft palate carcinoma.

Sagittal and axial illustrations demonstrate the potential spread patterns of a soft palate carcinoma (arrows). (From Mukherji SK, Pillsbury H, Castillo M: *Imaging squamous cell carcinomas of the upper aerodigestive tract: what the clinicians need to know*, *Radiology* 205:629-646.)

- Patterns of spread for soft palate carcinoma (Fig. 10-28):
 - Inferiorly to tonsillar pillars
 - Anteriorly to hard palate
 - Laterally deep invasion can occur into the parapharyngeal space
 - Superiorly, extension along the nasopharynx into the skull base

Squamous Cell Carcinoma of the Oropharyngeal Wall

Anatomic Considerations

- Posterior pharyngeal wall starts at the inferior aspect of the nasopharynx in the region of the soft palate and extends to the level of the epiglottis inferiorly:
 - Makes up the posterolateral surfaces of the oropharynx
 - Pharyngeal constrictor muscles constitute the framework of the pharyngeal walls.
 - Lateral aspect continuous with the pharyngoepiglottic fold and continues to the lateral aspect of the piriform sinus
 - Nerve supply from cranial nerves IX and X
 - Rich in lymphatics with primary drainage directed to retropharyngeal nodes and levels II and III

Clinical

- More common in men than women; most common in the seventh decade of life

- Clinically “silent” region resulting in tumors presenting at a more advanced stage (e.g., T3, T4):
 - Symptoms may include dysphagia, odynophagia, bleeding, and a neck mass.
 - Otalgia which represents referred pain in the ear region may be an initial symptom of oropharyngeal cancers is mediated by cranial nerves IX and X.
 - Clinically palpable lymph nodes present in:
 - 25% of T1 lesions
 - 30% of T2 lesions
 - 66% of T3 lesions
 - >75% of T4 lesions
 - Most pharyngeal wall tumors extend across the midline, commonly resulting in bilateral cervical metastases; retropharyngeal lymph nodes are also at increased risk.

Pathology

Histology

- Conventional invasive keratinizing squamous cell carcinoma is the most common histologic type:
 - Originates from surface epithelium, so intraepithelial dysplasia is often present and identifiable in the absence of ulceration
 - May be well, moderately, or poorly differentiated
 - Desmoplastic stromal response present
- Histologic variants of squamous cell carcinoma may occur.

Treatment and Prognosis

- TNM classification for pharyngeal carcinoma is detailed in Table 10-6.
- Treatment options must address the primary site and both sides of the neck, including the bilateral retropharyngeal nodes:
- Outcomes for early stage disease:
 - Primary RT:
 - Local control rates of 93% and 82% for T1 and T2, respectively
 - 5-year disease-specific survival and overall survival:
 - Stage I: 88% and 50%, respectively
 - Stage II: 89% and 75%, respectively
- Outcomes for advanced stage disease:
 - Primary RT:
 - 5-year local control rates of 59% and 44% to 50% for T3 and T4, respectively
 - 5-year disease-specific survival and overall survival:
 - Stage III: 49% and 31%, respectively
 - Stage IV: 35% and 21%, respectively
 - Outcomes for primary surgery with or without radiotherapy include:

- For combined therapy:
 - Local failure of 11%
 - 5-year survival rate of 35%
- For patients with local failure post-primary radiotherapy, 16% 5-year survival rate
- Patterns of spread for pharyngeal wall carcinoma:
 - Superiorly to nasopharynx
 - Posteriorly to prevertebral fascia
 - Inferiorly to piriform sinus and hypopharyngeal wall

Squamous Cell Carcinoma of the Hypopharynx

Definition: Hypopharyngeal carcinoma involves the piriform sinus, posterior pharyngeal wall, and postcricoid area.

Anatomic Considerations

- Piriform sinus: Inverted pyramid- or pear-shaped sinus composed of anterior, medial, and lateral walls converging inferiorly toward an apex at the level of the inferior border of the cricoid cartilage:
 - Superior border: at level of pharyngoepiglottic fold
 - Lateral wall: inner surface of thyroid cartilage and thyrohyoid membrane
 - Medial wall: posterior surface of the aryepiglottic fold and the arytenoids and cricoid cartilages
- Posterior pharyngeal wall: three levels of the pharynx are recognized, including the nasopharynx, oropharynx, and hypopharynx with no specific anatomic barriers between these levels; tumors of the pharynx tend to be large at presentation with involvement of more than one level
- Postcricoid area: bounded laterally by the piriform sinuses and extends from the posterior surface of the arytenoid cartilage to the inferior surface of the cricoid cartilage

Clinical

- More common in men than in women; peak incidence in the sixth to seventh decades of life:
 - 80% to 85% occur in men
 - For postcricoid specific carcinomas, 50% to 90% occur in women
- In descending order of occurrence, hypopharyngeal carcinomas involve the piriform sinus > posterior pharyngeal wall > postcricoid region:
 - Piriform sinus accounts for approximately 65% to 85% of the carcinomas in this region.
 - Posterior pharyngeal wall accounts for approximately 10% to 20% of the carcinomas in this region.
 - Postcricoid region accounts for approximately 5% to 15% of the carcinomas in this region.

- Symptoms include:
 - Dysphagia: most common presenting symptom, present in up to 85% of cases
 - Palpable neck mass most common physical finding
 - Other symptoms may include odynophagia, sore throat, sensation of a foreign body in the throat, hoarseness, referred otalgia, hemoptysis, and weight loss.
- Hypopharyngeal carcinomas tend to remain quiescent for longer periods and present with more advanced disease (i.e., T3 and T4):
 - Carcinomas of the postcricoid area are commonly extensive at presentation and portend a worse prognosis in comparison with carcinomas from other hypopharyngeal locations.
- Uncommonly, early stage hypopharyngeal carcinomas diagnosed in the evaluation of new-onset reflux symptoms
- Cause linked to:
 - Tobacco smoking
 - Excessive alcohol use
- Plummer-Vinson syndrome characterized by:
 - Dysphagia due to webs, stenosis, or mucosal atrophy:
 - Webs arise from anterior esophageal wall distal to the cricoid cartilage.
 - Carcinomas develop immediately proximal to the webs and not within the webs.
 - Carcinomas may develop in other sites including the oral cavity and esophagus.
 - Treatment with dietary supplements, particularly iron, may result in disappearance of the webs, thereby decreasing the incidence of carcinoma.
 - Iron-deficiency anemia
 - Glossitis
 - Cheilitis
 - Achlorhydria

Pathology

Gross

- Tumors of all hypopharyngeal sites tend to be large at presentation:
 - Those of the posterior hypopharyngeal wall often are greater than 5 cm in greatest dimension.

Histology

- Majority are invasive keratinizing moderately to poorly differentiated squamous cell carcinomas.

Treatment and Prognosis

- TNM classification for pharyngeal carcinoma is detailed in [Table 10-6](#).
- For early stage patients, including stage I or II (T1-2, N0), constituting approximately 10% to 15% of

hypopharyngeal carcinomas, important goal in management is to obtain local control while optimizing functional outcome:

- Curative radiation is preferred as definitive treatment approach, provides good chance for organ preservation.
- Alternatively, open or endoscopic surgery (partial laryngopharyngectomy) with ipsilateral or bilateral neck dissection may be performed.
- More recently, transoral laser microsurgeries used with promising results
- For advanced stage patients, including stage III to IVa (T1-2, node positive, or T3-4a):
 - Desire for organ preservation in locally advanced disease is primary indication for nonoperative management in patients who may be technically respectable
 - Definitive chemoradiotherapy represents treatment most used:
 - Induction chemotherapy can be used prior to definitive therapy.
 - For patients undergoing primary radiation or chemotherapy, consideration should be given to postradiation neck dissection.
 - Generally not used for N0-N1 necks
 - Used for patients with N2-N3 neck disease in attempt to enhance regional disease control
 - Primary surgery and postoperative radiation:
 - Total laryngectomy and partial pharyngectomy with bilateral neck dissections was historical mainstay of treatment for locally advanced hypopharyngeal cancers.
 - Postoperative radiation:
 - Indications for postoperative radiation therapy include:
 - Pathologic T3-T4 tumors (bulky T-stage disease)
 - N2-N3 disease
 - Positive surgical margins
 - Perineural invasion
 - Lymph-vascular invasion
 - Extranodal extension of involved lymph nodes
 - Induction chemotherapy
 - Can be used to facilitate organ preservation in some patients who require total laryngectomy for adequate surgical resection
- For unresectable, nonmetastatic disease:
 - May warrant aggressive treatment with curative intent or may be best served by a palliative approach with decision making predicated on tumor burden, patient motivation, and performance status
 - Curative intent therapy may include chemoradiation:
 - For patients with high motivation and good performance status, induction chemotherapy followed by chemoradiation may be considered.
 - Patients with advanced disease and poor performance status who are not considered appropriate for aggressive radiation or chemoradiation can be offered palliative radiotherapy alone.
 - In conjunction with radiation therapy represents a potential legitimate alternative therapy to surgery in:
 - Patients with advanced hypopharyngeal carcinoma who want to avoid total laryngectomy
 - Patients with unresectable M0 hypopharyngeal carcinoma:
 - Unresectability (or not resectable for cure) includes tumor fixed to the cervical spine, massive T4 disease, bulky lymphadenopathy fixed to neurovascular bundle
 - Patients with M1 hypopharyngeal carcinoma
- Outcomes:
 - Outcomes for hypopharyngeal carcinomas are poor:
 - 5-year overall survival rates of approximately 30%
 - 5-year stage-specific overall survival includes:
 - Stage I: 51.3%
 - Stage II: 34.8%
 - Stage III: 34.8%
 - Stage IV: 19.8%
 - Poor prognostic factors include:
 - Increasing age (>70 years)
 - Male gender
 - Carcinomas of the posterior wall and postcricoid area
- Hypopharynx is rich in lymphatic spaces and many patients (65% to 80%) have node-positive disease:
 - Greater than 50% present with clinically positive cervical lymph nodes
 - Additional 30% to 40% of N0 necks found to show pathologic involvement when dissected electively
 - Lymphatic drainage includes jugular chain nodes (levels II to IV) as well as retropharyngeal nodes
 - In addition, paratracheal lymph nodes also at risk in hypopharyngeal cancers with surgical specimens showing involvement in 20% to 25% of cases
 - Bilateral neck disease is common owing to presence of cross-draining lymphatics.
- Hypopharyngeal carcinomas have higher rates of distant metastatic disease than primary carcinomas of other head and neck subsites:
 - Approximately 16% present with distant metastasis at diagnosis

Fig. 10-29. Patterns of spread for piriform sinus carcinoma.

Sagittal and axial illustrations demonstrate the potential spread patterns of a piriform sinus carcinoma (arrows). (From Mukherji SK, Pillsbury H, Castillo M: *Imaging squamous cell carcinomas of the upper aerodigestive tract: what the clinicians need to know*, Radiology 205:629-646, 1997.)

- Lung is most common site of distant metastases followed by mediastinal lymph nodes, liver, and bone
- Hypopharyngeal carcinomas tend to grow submucosally, spreading beneath intact mucosa and beyond grossly apparent margins.

Patterns of Spread

- Piriform sinus carcinomas (Fig. 10-29):
 - Medially to invade the lateral wall of the supra-glottic larynx with invasion of the cricoarytenoid joint and/or muscle or the recurrent laryngeal nerve resulting in vocal cord fixation
 - Laterally to invade posterolateral portion of the thyroid cartilage and/or invasion of the superior lobe of the thyroid gland
 - Superiorly to involve aryepiglottic folds, arytenoids, paraglottic space, and base of tongue
 - Across the postcricoid areas with involvement of the opposite piriform sinus
 - Into the contiguous posterior pharyngeal wall, which is common as the tumor grows laterally
- Posterior hypopharyngeal wall carcinomas:
 - May spread circumferentially to involve the larynx
 - Advanced carcinomas may extend superiorly with involvement of the tonsillar pillars, soft palate, and nasopharynx.

- Advanced carcinomas may extend inferiorly with involvement of the piriform sinus, cricopharyngeus, and cervical esophagus.
- Postcricoid area carcinomas:
 - Inferiorly to involve cervical esophagus
 - Circumferential growth frequently occurs with invasion of cricoid cartilage and cricoarytenoid muscles and resultant vocal cord fixation.
 - May spread circumferentially to involve the larynx
 - Advanced carcinomas may extend superiorly with involvement of the tonsillar pillars, soft palate, and nasopharynx.
 - Advanced carcinomas may extend inferiorly with involvement of the piriform sinus or cervical esophagus.
 - Deep infiltration can involve retropharyngeal space with access to lymphatics in that region and subsequently into the prevertebral fascia.

Other Variants of Squamous Cell Carcinoma of the Pharynx

- Other variants of conventional squamous cell carcinoma that may occur in the oropharynx include:
 - Verrucous carcinoma
 - Papillary squamous cell carcinoma
 - Spindle cell squamous carcinoma
 - Adenosquamous carcinoma
 - Other rare variants
- For a detailed discussion of these histologic variants, see Section 5, Larynx.
- Some of these oropharyngeal SCC variants may be associated with HPV including:
 - Papillary SCC
 - Spindle cell squamous carcinoma
 - Adenosquamous carcinoma (Fig. 10.30)

Neuroendocrine Carcinomas

- Neuroendocrine carcinomas (NEC) represent a heterogeneous group of malignant neoplasms with divergent differentiation along epithelial and neuroendocrine cell lines.
- See Section 5, Larynx, for a more detailed discussion of neuroendocrine carcinomas.
- Of note is the presence of HPV in association with small cell neuroendocrine carcinoma that occurs primarily in the oropharynx.
- Rare tumor type in the pharynx; however, of note is the existence of HPV-associated small cell neuroendocrine carcinoma primarily arising in the oropharynx.

Fig. 10-30. Tonsillar HPV-associated adenosquamous carcinoma.

A, This was a deeply infiltrative tonsillar carcinoma comprised of an admixture of cells with squamous differentiation and glandular differentiation. **B**, Diffuse and strong p16 immunoreactivity in both squamous cell and glandular components. Additional findings seen but not shown included the presence of high-grade intraepithelial dysplasia, diffuse and strong p63 immunoreactivity for cytokeratins (AE1/AE3, CAM5.2, CK5/6) and p63, absence of staining with neuroendocrine markers (e.g., synaptophysin, others), and molecular confirmation for the presence of HPV.

Oropharyngeal HPV-Associated Small Cell Undifferentiated Neuroendocrine Carcinoma (Fig. 10-31)

Definition: Neuroendocrine carcinoma with small cell morphology associated with HPV infection as well as history of tobacco and/or alcohol abuse:

- In contrast to the relatively favorable prognosis associated with HPV-associated squamous cell

carcinomas of the oropharynx, the reported follow-up of patients with oropharyngeal HPV-associated neuroendocrine carcinoma suggests an aggressive behavior despite its association with HPV.

- Also referred to as small cell carcinoma

Clinical

- Uncommon tumor with less than 20 cases reported in the literature
- Much more common in men than women; occur over a wide age range from 35 to 87 years, with a mean age of 59 years
- Symptoms include sore throat, epistaxis, or neck mass.
 - Additional symptoms may include severe headache, hemoptysis, and altered speech.
- Patients often present with advanced clinical stage disease:
 - Initial presentation may include metastatic disease with or without known primary oropharyngeal lesion including to:
 - Cervical lymph nodes
 - Lung
 - Brain
 - Uncommon for primary tumor to be localized to the oropharynx without metastatic disease
- Sites of origin include the palatine tonsil, base of tongue, and lateral pharynx:
 - Tonsillar and base of tongue cancers may extend into the pharynx.
- 64% (9 of 14) of patients reported had known risk factors, including tobacco and/or alcohol abuse.

Pathology

- Histomorphology is that of a poorly differentiated neuroendocrine carcinoma (small cell carcinoma) analogous to that of its pulmonary counterpart, including:
 - Trabecular, nested, organoid, and/or solid growth patterns composed of small to moderately sized cells with increased nuclear-to-cytoplasmic ratio, scant to moderate amounts of pale eosinophilic cytoplasm, and indistinct cell borders
 - Stippled (so-called salt and pepper) nuclear chromatin with absence of nucleoli
 - Nuclear molding may be present.
 - Marked increase in mitotic activity, including atypical forms and necrosis (individual cell and confluent foci)
- Neural rosette-like structures may rarely be present.
- Other histomorphologic tumor types seen in association with the neuroendocrine carcinoma may include:
 - Squamous cell carcinoma, nonkeratinizing and basaloid morphology

Fig. 10-31. HPV-associated small cell undifferentiated neuroendocrine carcinoma (small cell carcinoma).

A, Hypercellular diffusely infiltrative neoplasm with trabecular and solid growth. **B**, Small to moderate-size cells with stippled nuclear chromatin, absent nucleoli, nuclear molding, increase in mitotic activity, and necrosis (confluent foci and individual cell); immunoreactivity includes **(C)** punctate (dot-like) paranuclear cytokeratin (CAM5.2) staining; **D**, synaptophysin staining; and **(E)** p16 staining. Molecular analysis confirmed the presence of HPV (not shown).

- Immunohistochemistry for small cell component:
 - Immunoreactivity for synaptophysin, chromogranin, CD56, and neuron-specific enolase with variable staining for TTF1
 - Positive for cytokeratins, including punctate paranuclear staining for AE1/AE3 and CAM5.2:
 - CK7 and CK20 may be positive.
 - CK5/6 negative in small cell component
 - Variability of p63 staining reported, including:
 - Reported positivity from focal to diffuse in small cell component in one study
 - Limited positive to squamous cell component and absence in small cell component in another study
 - Two cases analyzed by in situ hybridization (ISH) for Epstein-Barr encoded RNA (EBER) were negative.
- HPV analysis
 - 92% (12 of 13) p16 positive with strong and diffuse staining
 - 80% (8 of 10) in situ hybridization for HPV 16 positive
 - 50% (3 of 6) p16 positive were positive for HPV by PCR

Treatment and Prognosis

- Majority of patients presented with advanced disease, including locoregional nodal metastasis or distant metastases to the lung and brain.
- Treatment includes surgical excision followed by chemotherapy and/or radiation.
- High percentage of patients with local recurrence, locoregional metastasis, and/or distant metastasis:
 - Distant metastatic sites include brain, bone, pleura, lung, pancreas, or adrenal gland.
- One study reported 60% (3 of 5) of patients died of disease with follow-up of 6 to 15 months (mean survival 10 months).
- In contrast to the relatively favorable prognosis associated with HPV-associated squamous cell carcinomas of the oropharynx, the findings of the HPV-associated neuroendocrine carcinoma of the oropharynx suggest an aggressive behavior despite its association with HPV.

Malignant (Minor) Salivary Gland Tumors

- For more detailed discussion see Section 6, Salivary Glands.
- Malignant salivary gland tumors of the oropharynx and nasopharynx are uncommon.
- All subtypes of malignant salivary gland tumors may occur in minor salivary gland sites but the most common types include:

- Mucoepidermoid carcinoma
- Adenoid cystic carcinoma
- Polymorphous low-grade adenocarcinoma
- Some of the more common malignant major salivary gland tumors are uncommon in minor salivary gland locations, including acinic cell adenocarcinoma; a minor salivary gland neoplasm that engenders the diagnostic consideration of an acinic cell adenocarcinoma should raise concern for the likelihood of an alternative diagnosis such as mammary analogue secretory carcinoma (see Section 6, Salivary Glands).
- Select malignant salivary gland carcinomas, including polymorphous low-grade adenocarcinoma and clear cell carcinoma (nonhyalinizing and hyalinizing type), predilect to minor salivary glands, in particular, of the oral cavity.
- All minor salivary gland tumors are unencapsulated; as such, the differentiation of a benign tumor from a malignant tumor is often predicated on the presence or absence of invasion; invasion includes:
 - Into adjacent minor salivary gland parenchyma
 - Into fibroconnective tissues (e.g., fat, skeletal muscle)
 - Peri- and intraneural invasion (i.e., neurotropicism)
 - Lymph-vascular space invasion
 - Extension to and/or into the surface epithelium is not diagnostic of invasion or malignancy.
 - Metastatic disease is essentially diagnostic of a malignant neoplasm.

Low-Grade Nasopharyngeal Papillary Adenocarcinoma

(Fig. 10-32)

Definition: Surface epithelial-derived malignant tumor with adenocarcinomatous differentiation and an indolent biologic behavior.

- Light microscopic findings and the immunohistochemical profile support derivation of this neoplasm from the surface epithelium rather than from the subjacent minor salivary glands.

Synonym: Thyroid-like (low-grade) nasopharyngeal papillary adenocarcinoma

Clinical

- Uncommon primary tumor of the nasopharynx
- No gender predilection; occurs over a wide age range from the second through seventh decades of life (median, 37 years)

Fig. 10-32. Low-grade nasopharyngeal papillary adenocarcinoma (LGNPPA).

A, Infiltrative neoplasm showing complex papillary growth. **B**, Origin from the nasopharyngeal surface epithelium is seen with transition from normal nasopharyngeal surface epithelium to the neoplastic papillary proliferation. **C**, Complex papillary and glandular growth patterns; scattered cluster of foamy histiocytes is present (*right side of image*). **D**, At high magnification the nuclei show cytomorphologic features similar to those seen in thyroid papillary carcinoma including nuclear irregularities in size and shape, optically clear to dispersed (very fine) appearing nuclear chromatin, and nuclear crowding and overlapping. **E**, Psammoma bodies characterized by the presence of concentric laminations can be present; lesional cells are immunoreactive for **(F)** thyroid transcription factor 1 (TTF-1) (nuclear staining) but **(G)** are negative for thyroglobulin.

Continued

Fig. 10-32, cont'd

- May occur anywhere in the nasopharynx but is most common in the posterior and lateral nasopharyngeal walls and the roof
- Most common symptom is nasal obstruction:
 - Other symptoms may include otitis media with or without associated hearing deficits and postnasal drip.
- No known etiologic factors:
 - A single case reported in association with Turner syndrome
 - No association with EBV or HHV-8

Pathology

Gross

- Exophytic, soft to gritty mass with a papillary, nodular, and cauliflower-like appearance and varying in size from a few millimeters to 3.0 cm

Histology

- Surface epithelial derivation is identified by transition areas from normal nasopharyngeal surface epithelium to neoplastic proliferation:
 - Transitional areas may only be focally identified but may also be absent in any given case.
- Unencapsulated and infiltrative tumor composed of papillary and glandular growth patterns:
 - Papillary structures are complex with arborization and hyalinized fibrovascular cores.
 - Complex glandular pattern characterized by back-to-back and cribriform growth
- Cytomorphology:
 - Cells vary in appearance from pseudostratified columnar to cuboidal.
 - Nuclei are round to oval with vesicular to optically clear-appearing chromatin pattern.
 - Cytoplasm is eosinophilic.

- Nuclear pleomorphism and loss of basal polarity are seen.
- Mitoses and prominent nucleoli are not commonly identified.
- Psammoma bodies and necrosis can be identified.
- Rare examples may show prominent spindle cell component:
 - Spindle cells display nuclear features similar to the epithelial component.
 - Two cell types may merge imperceptibly.
- Histochemistry:
 - Evidence of epithelial mucin as seen by the presence of:
 - Intracytoplasmic diastase-resistant, PAS-positive material
 - Intracytoplasmic and intraluminal mucicarmine material
- Immunohistochemistry:
 - Diffusely positive reactivity with cytokeratins, epithelial membrane antigen (EMA), and thyroid transcription factor 1 (TTF-1) (nuclear)
 - Focal reactivity with carcinoembryonic antigen (CEA)
 - No immunoreactivity with thyroglobulin, S100 protein, calcitonin, p63, or glial fibrillary acidic protein (GFAP)
 - Low proliferation indices by Ki67 of less than 5%
- Cytogenetics and molecular genetics
 - No mutations reported at position 1799 (exon 15) in the *BRAF* gene (*BRAFV600E*) or in exons 9 and 11 of the *KIT* gene

Differential Diagnosis

- Papilloma (surface epithelial or minor salivary gland origin)
- Minor salivary gland neoplasms:
 - Mucoepidermoid carcinoma
 - Acinic cell carcinoma
 - Polymorphous low-grade adenocarcinoma
- Metastatic papillary thyroid carcinoma:
 - Histologic similarities, especially nuclear changes and psammoma bodies, exist between low-grade nasopharyngeal papillary adenocarcinoma and thyroid papillary carcinoma, requiring immunohistochemical stains for differentiation:
 - Thyroglobulin immunoreactivity is present in metastatic papillary thyroid carcinoma and absent in nasopharyngeal low-grade papillary adenocarcinoma.
 - TTF-1 may be present in both tumor types and is not a differentiating stain.

Treatment and Prognosis

- Complete surgical excision via a transpalatal approach is the preferred treatment and is curative.

- Endoscopic resection via combined transnasal and transoral approach may be effective.
- Radiotherapy (preoperative and postoperative) does not appear to be warranted.
- Slow-growing tumor with the potential to recur if incompletely excised
- Metastatic disease does not occur.

HEMATOLYMPHOID MALIGNANT NEOPLASMS

General Considerations

- Classification schemes of lymphomas have varied to include the Rappaport Classification (1966), National Cancer Institute Working Formulation (1982), Lukes-Collins Revised Classification (1992), and Revised European-American Lymphoma (REAL) Classification (1994); currently, the WHO Classification (2007) is a modification of the REAL Classification.
- The fourth edition of the WHO Classification stratifies neoplasms primarily according to lineage to include:
 - Myeloid
 - Lymphoid
 - Histiocytic/dendritic
 - In addition, the fourth edition of the WHO Classification incorporates new information including:
 - New defining criteria for some diseases
 - New entities defined by genetic criteria or by their morphology, immunophenotype, and clinical features.
- Lymphomas are subdivided into non-Hodgkin lymphomas (NHLs) and Hodgkin lymphomas:
 - In the head and neck, NHLs are more common.
- The vast array of clinical and pathologic features of the malignant lymphoproliferative diseases is well beyond the scope of this text; the approach here is to describe the more common types of malignant lymphomas affecting the extranodal lymphoid sites of the head and neck primarily of Waldeyer tonsillar ring; other site-specific malignant lymphomas are discussed in those specific sections to include:
 - NK/T cell in Section 1 on the sinonasal tract
 - Salivary gland malignant lymphomas in Section 6
 - Thyroid gland malignant lymphomas in Section 8
- Majority of malignant lymphomas of Waldeyer tonsillar tissues are B-cell lymphomas, including a wide spectrum of histologic types:
 - Diffuse large cell B-cell lymphoma (DLBCL) is most common.
 - Follicular low-grade lymphomas are uncommon.
- Mucosa-associated lymphoid tissue (MALT) gives rise to a variety of extranodal malignant lymphomas, including head and neck sites (nasopharyngeal, tonsil, salivary glands, and others):
 - Less than 4% of low-grade lymphomas of Waldeyer tonsillar ring are MALT lymphomas.
 - MALT-lymphomas share clinical, histologic, and immunohistochemical features, including:
 - Tendency to remain localized, evolve slowly, and be of B-cell phenotype
- AIDS patients may develop malignant lymphomas originating in head and neck sites or involving this region as part of a systemic process.
- Primary Hodgkin lymphoma occurring in the head and neck is predominantly nodal-based (e.g., cervical lymph nodes):
 - In general, primary Hodgkin lymphoma in mucosal sites and extranodal lymphoid tissues of the head and neck, including Waldeyer tonsillar tissues, are exceedingly uncommon and are not discussed.
- Cause for most lymphomas is unknown:
 - Some cases are associated with immunosuppression, including:
 - Posttransplant lymphoproliferative disorder (PTLD)
 - HIV/AIDS
 - Viruses may play a role in some lymphoma types.

Lymphomas of the Waldeyer Tonsillar Ring (Nasopharynx, Tonsils, and Base of Tongue)

Definition: Primary malignant lymphoid cell neoplasms with the bulk of tumor formed by a ring or group of extranodal lymphoid tissues about the upper end of the pharynx, including the palatine tonsils, pharyngeal tonsils (adenoids) and base of tongue.

Clinical

- Most common primary site for lymphomas that arise in the upper aerodigestive tract accounting for:
 - Approximately 5% to 10% of NHL in Western countries
 - Approximately 20% to 25% of NHL in Asian countries
 - Approximately 16% of all head and neck NHL
 - Approximately 50% of all NHL that are primary in the head and neck
- Majority (approximately 80%) are primary to the site of involvement with a minority representing secondary involvement to an NHL at another site.
- Most common type of NHL of Waldeyer tonsillar ring is diffuse large B-cell lymphoma; less common types of NHLs of these sites include:

- Extranodal marginal zone lymphoma (MALT lymphoma)
- Mantle cell lymphoma
- Follicular lymphoma
- Burkitt lymphoma
- Others
- More common in men than women; occurs over a wide age range but is most common in the sixth to eighth decades of life:
 - Patients with underlying immunodeficiency condition usually are younger.
- Most common sites of occurrence in descending order of frequency are:
 - Tonsils > nasopharynx > base of tongue
- Most common symptoms include dysphagia, odynophagia, swelling or lump in throat, decreased hearing, pain, and sore throat:
 - Majority of masses are unilateral (80% to 90% of cases)
 - Cervical adenopathy is present in approximately 65% of patients.
 - Systemic symptoms (e.g., fever, night sweats, other) not common
 - Multifocality may be present.
- Cause:
 - No known cause in the majority of patients
 - Minority of patients have an underlying/associated immunodeficiency condition that may predispose to NHL, including:
 - Post-transplantation, HIV infection/AIDS
 - Association of NHL, especially diffuse large B-cell lymphoma, with Epstein-Barr virus is considered weak.

Pathology

Gross

- Often large exophytic submucosal mass with or without surface ulceration

Histology

Diffuse Large B-Cell Lymphoma (DLBCL)
(Figs. 10-33 and 10-34)

- Although any NHL type can occur in Waldeyer ring, the most common NHL is DLBCL, representing from 60% to 84% of NHL of these sites.
- Diffuse submucosal dyscohesive cellular infiltrate with:
 - Effacement of normal architecture, including absence/loss of germinal centers, although due to incomplete involvement residual germinal centers may be identified
 - Neoplastic cells are composed of medium to large cells with large round to oval vesicular (non-cleaved) nuclei and several membrane-bound

Fig. 10-33. Nasopharyngeal DLBCL.

Left lateral nasopharyngeal diffuse large B-cell lymphoma that demonstrates increased FDG activity on PET/CT examination. A nasopharyngeal carcinoma could have a similar imaging appearance, and tissue specimen examination is the final arbiter for diagnosis, as imaging appearances are often nonspecific. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 29-38, p 1773.)

- small nucleoli or a single centrally located prominent eosinophilic nucleolus
- Nuclear lobulation may be present.
- Mitotic activity, including atypical forms, (coagulative) necrosis, and apoptotic figures can be seen.
- Surface epithelium may be intact or ulcerated; crypt epithelium is usually intact.
- Immunohistochemistry:
 - Positive reactivity with pan-hematolymphoid marker CD45 (leukocyte common antigen [LCA]) and one or more pan-B-cell markers, including CD20, CD79a, PAX5
 - Surface or cytoplasmic immunoglobulin positive (IgM > IgG > IgA)
 - Melanoma-associated antigen (MUM1) expression (nuclear staining):

Fig. 10-34. Diffuse large B-cell lymphoma of the tonsil.

A, Unilateral marked tonsillar enlargement. **B**, Effacement of the normal tonsillar architecture by a diffuse cellular proliferation. **C**, Foci of confluent necrosis (*bottom right*). **D** and **E**, Diffuse dyscohesive cellular infiltrate composed of large cells with large round to oval vesicular (noncleaved) nuclei, prominent eosinophilic nucleoli, and increased mitotic activity (*arrowheads* in **D**). Occasionally, cohesive growth suggesting a possible epithelial neoplasm (i.e., carcinoma) can be identified (not shown). Lesional cells are immunoreactive for **(F)** CD45, **(G)** CD20, and **(H)** MUM1 (nuclear). **I**, Lymphomas including DLBCL may show p63 immunoreactivity.

Continued

Fig. 10-34, cont'd

- *MUM1* gene encodes a transcription factor responsible for development of B, T, plasma, dendritic, and myeloid cells
- *MUM1* expression originally recognized by upregulation in multiple myeloma; however, not specific for plasmacytic differentiation and can be seen in a variety of neoplasms including:
 - DLBCL
 - Follicular lymphoma
 - Burkitt lymphoma
 - Hodgkin lymphoma
 - Anaplastic large cell lymphoma
 - Lymphoplasmacytic lymphoma
 - Chronic lymphocytic leukemia
 - Marginal zone lymphoma
 - Primary mediastinal large B-cell lymphoma
 - Primary effusion lymphoma
 - Melanoma
- *BCL6* in approximately 60%
- *CD10* expression in 40%
- *CD5* and *CD30* in approximately 10%
- Cyclin D1 (*BCL1*) negative
- High proliferation index by Ki67 of >20% and often >80%
- p53 positive in approximately 40%
- p63 may be positive (usually focal/scattered positive cells)
- Absence of expression for T-cell markers (*CD3*, others)
- Absence of epithelial, melanocytic, neuroendocrine, and myogenic markers
- Hans algorithm subclassifies DLBCL into germinal center B-cell type (GCB) versus non-germinal center B-cell type (non-GCB) with very high concordance with the gene expression profiling (GEP):
 - GCB: *CD10*+, *BCL6*+, *MUM1*–
 - Non-GCB: *CD10*–, *BCL6*+, *MUM1*+
 - GCB DLBCL may have better prognosis than non-GCB DLBCL.

- Cytogenetics and molecular genetics:
 - Clonal rearranged immunoglobulin heavy- and light-chain genes
 - *BCL2* and *BCL6* rearranged in approximately 20% and 30%, respectively
 - *BCL6* mutation in approximately 70%
 - Mutations of *TP53* in approximately 22%
 - *MYC* rearranged in less than 10%:
 - *MYC* rearrangement is a molecular hallmark of Burkitt lymphoma
 - In DLBCL *MYC* rearrangement more frequent in HIV-infected patients and in extranodal lymphomas
 - Usually EBV negative except in setting of immunodeficiency
 - CGH studies show various chromosomal gains and losses.

Differential Diagnosis

- Reactive lymphoid (follicular) hyperplasia
- Infectious-related lymphoid enlargements:
 - Infectious mononucleosis
 - HIV-associated lymphoid lesions
- Nasopharyngeal carcinoma, nonkeratinizing undifferentiated type:
 - Presence of cytokeratins and EBER and absence of CD45 and B-cell marker differentiate carcinoma from lymphoma.
- Mucosal malignant melanoma
- Rhabdomyosarcoma
- Peripheral T-cell lymphomas:
 - Represent less than 15% of Waldeyer ring NHL
 - Most show angiocentric features
 - Uncommonly, anaplastic large cell lymphoma (ALCL) occur (see below).

Treatment and Prognosis

- Treatment primarily includes multiagent chemotherapy and radiotherapy:
 - Multi-agent chemotherapy includes cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) plus ant-CD20 (Rituximab).
 - Surgical resection may be needed for symptomatic relief.
- Majority (80%) of NHL of Waldeyer tonsillar ring have localized disease/low clinical stage (i.e., Stage IE, IIE), see [Table 10-8](#) (Ann Arbor Staging System):
 - There is a tendency to spread to cervical lymph nodes.
- For B-cell lymphomas, including DLCL, the prognosis is dependent on the clinical stage:
 - Overall 10-year disease-free survival (for all treatment modalities) is approximately 66%.
 - Overall survival rate of 82%
 - Relapse occurs in 30% to 45% of patients:
 - May be localized to cervical lymph nodes
 - May involve non-head and neck sites, primarily the gastrointestinal tract (GIT), in up to

TABLE 10-8 Ann Arbor Staging System for Lymphomas

Stage	Definition
I	Single lymph node region or
IE	Single extralymphatic organ* or site
II	Two or more lymph node regions on the same side of the diaphragm
IIE	Localized involvement of an extralymphatic organ and one or more lymph node regions on the same side as the diaphragm
III	Lymph node involvement on both sides of the diaphragm
IIIE	Stage III accompanied by localized involvement of an extralymphatic organ
IIIS	Stage III accompanied by involvement the spleen
IIISE	Stage III accompanied by localized involvement of an extralymphatic organ and the spleen
IV	Diffuse or disseminated involvement of one or more extralymphatic organs or tissues with or without associated lymph node enlargement
A	Without B symptoms [†]
B	With B symptoms [†]

*Extralymphatic organs defined as those other than lymph node, spleen, thymus, Waldeyer ring, appendix, and Peyer patches.

[†]B symptoms include fever (38°C), drenching night sweats, and loss of more than 10% original weight within 6 months.

20% of patients (GIT involvement may also occur at the initial presentation or even prior to involvement of Waldeyer ring, necessitating clinical evaluation of these sites)

– Less commonly may involve other sites, such as bone marrow, liver, spleen

- Factors associated with adverse prognosis include (International Prognostic Index for Prognostication of Non-Hodgkin Lymphoma, [Box 10-3](#)):
 - Age of patient ≥ 60
 - Advanced clinical stage (III or IV)
 - Number of extranodal sites of involvement (≥ 1)
 - Poor performance status (score of 2 or higher)
 - Abnormal serum LDH level
 - Tumor bulk
 - Presence of B symptoms:
 - B symptoms include fever (38° C), drenching night sweats, and loss of more than 10% original weight within 6 months.

Other Histologic Types of NHLs

- Less common histologic types of NHLs occurring in Waldeyer tonsillar ring include:
 - Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma):

BOX 10-3 International Prognostic Index for Prognostication of Non-Hodgkin Lymphoma**Parameters**

- Age: ≥ 60 years
- Stage: Advanced stage (III or IV)
- Number of extranodal sites of involvement: ≥ 1
- Performance status: ≥ 2
- Serum LDH level: Abnormal

International Prognostic Index

- Total number of preceding features that are present

Risk Group Stratification According to the Index

- 0-1: Low risk
- 2: Low intermediate risk
- 3: High intermediate risk
- 4-5: High risk

- In the head and neck, most often involve tonsils; less often other sites (e.g., oral cavity, others)
- Precursor lesions:
 - Unlike MALT lymphomas of other extranodal sites, there is no known association with infectious microorganisms or autoimmune-based chronic inflammatory disorder in the development of MALT lymphoma of Waldeyer tonsillar ring
 - Infectious diseases associated with extranodal MALT lymphomas include:
 - *Helicobacter pylori* with gastric MALT lymphoma
 - *Chlamydia psittaci* with ocular MALT lymphoma
 - *Campylobacter jejuni* and *Borrelia burgdorferi* with cutaneous MALT lymphoma
 - Autoimmune-based chronic inflammatory disorders known to precede development of site-specific MALT lymphoma include:
 - Sjögren syndrome with salivary gland MALT lymphoma
 - Autoimmune thyroiditis with thyroid MALT lymphoma
- Parafollicular, interfollicular, or diffuse proliferation of marginal zone cells
- Most characteristic cell is a small to medium cell with irregular (folded) or elongated nuclei, moderately dense chromatin, inconspicuous nucleoli, and scanty pale to clear-appearing cytoplasm; this appearance is centrocyte-like
- Neoplastic cells may colonize lymphoid follicles.
- Invasion of epithelium (i.e., surface or crypt epithelium, minor salivary glands) forming lymphoepithelial lesions is a distinctive feature

but is not unique to MALT lymphoma and can be present in other lymphomas and in reactive lymphoid proliferations.

- Cells with monocytoid B-cell-like appearance with abundant, clear cytoplasm may be present especially in and around the epithelial structures, resulting in pale collars around the lymphoepithelial lesions:
 - This feature more prominently seen in association with salivary gland (see Section 6)
- Plasma cells may be intermingled with the neoplastic cells:
 - May appear mature (bland appearing) or atypical features including:
 - Enlarged nuclei, distinct nucleoli, Dutcher bodies, crystalline cytoplasmic inclusions
- May be monotypic, representing a part of the neoplasm
- May be so prominent as to suggest a possible diagnosis of extramedullary plasmacytoma
- Increased numbers of large B-cells may be identified in some cases consistent with progression to diffuse large B-cell lymphoma.
- Immunohistochemistry:
 - CD45, CD20, CD79a positive
 - Express IgM > IgA or IgG and show light chain restriction
 - bcl-2 positive in neoplastic cells and in colonizing B-cells but not in residual/reactive germinal centers
 - Co-expression of CD43 may be seen
 - CD5, CD10, CD23, cyclin D1, and bcl6 negative:
 - Infrequently, CD5 may be positive
 - CD21 and CD35 (marginal cell-associated antigens) may be positive:
 - Staining also reveals expanded meshwork of follicular dendritic cells corresponding to colonized follicles
 - Ki67 index is low.
 - EBV negative
- Plasmacytic differentiation may be seen and may predominate in any given tumor simulating a plasmacytoma:
 - In this setting, immunohistochemical stains will be helpful in differentiating a malignant lymphoma with plasmacytic differentiation (CD45 and CD20 positive) from a plasmacytoma (CD45 negative, usually CD20 negative and CD138 positive)
- Cytogenetics and molecular genetics:
 - t(11;18)(q21;q21) occurs in approximately 35% of cases:
 - Seen mainly in pulmonary and gastric tumors

- $t(14;18)(q32;q21)$ occurs in approximately 15% of cases:
 - Found predominantly in salivary gland, eye, skin, and lung tumors
- $t(3;14)(p14.1;q32)$ seen in up to 10% of cases:
 - Found predominantly in thyroid, eye, and skin tumors
- $t(1;14)(p22;q32)$ occurs in 1% to 2% of cases:
 - Appears to be associated with more disseminated or aggressive tumors
- Other genetic changes include:
 - Trisomy 3, 12, and 18
 - Loss of heterozygosity or mutation of TP53
- Indolent neoplasm with tendency to be localized to the involved site for extended periods of time prior to dissemination:
 - High proportion of cases treated by locoregional therapy
- Radiosensitive tumors
- Most patients have early stage disease (stage I/II) at presentation
- In spite of apparent indolent behavior, local or systemic dissemination may occur more frequently than initially believed.
- Involvement of multiple extranodal sites and bone marrow involvement do not appear to portend worse prognosis.
- Prognosis is favorable:
 - 5-year overall survival according to the NHL Classification project is 74%.
 - Relapse rate of 37% with median time to relapse of 47 months
 - Transformation to large cell lymphoma portends worse prognosis.
- Anaplastic large cell lymphoma (ALCL), anaplastic lymphoma kinase (ALK)-positive (Fig. 10-35)
 - ALK+ lymphoma of T-cell lineage characterized by large cells with abundant cytoplasm and pleomorphic, often horseshoe-shaped nuclei that by definition shows chromosomal translocation, implicating the *ALK* gene and expression of ALK protein and expression of CD30
 - Male predominance; most frequent in first 3 decades of life
 - Primarily affects lymph nodes, but extranodal disease occurs, including:
 - Most commonly, skin (primary cutaneous ALCL), bone, soft tissue, lung, liver, gastrointestinal tract
 - Less commonly mucosal sites of the head and neck (especially in HIV-positive patients)
- Histology:
 - Hallmark lesional cells are large with pleomorphic nuclei many of which are characterized by eccentric location, kidney- or horseshoe-shaped appearance, perinuclear eosinophilic Golgi zone region, multiple relatively small nucleoli rather than a single large one, and abundant amphophilic to basophilic cytoplasm
 - In addition to the hallmark larger cells, a population of smaller cells with similar cytomorphologic features may be seen aiding in the diagnosis
 - Multinucleated giant cells, some resembling Reed-Sternberg cells, may be prominently identified.
 - Increased mitotic activity is present.
 - Admixture of inflammatory cells including mature lymphocytes, plasma cells, histiocytes, eosinophils, and neutrophils may be present.
- In lymph nodes, malignant cells characteristically infiltrate nodal sinuses simulating sinus histiocytosis or a metastatic neoplasm; cohesive growth of tumor cells may be seen in the paracortical region.
- In cutaneous or mucosal sites, may be associated with pseudoepitheliomatous hyperplasia
- Immunohistochemistry:
 - CD30 (Ki-1) positive in virtually all tumor cells:
 - Staining pattern includes cell membrane and/or in Golgi region
 - ALK-1 (60% to 85%)-cytoplasmic and/or nuclear staining
 - Epithelial membrane antigen (EMA) in a majority (>80%) of cases:
 - Staining pattern similar to the CD30 staining
 - Majority of cases express one or more T-cell markers; however, due to loss of several pan-T-cell antigens often necessary to stain for multiple T-cell markers:
 - CD3 positive in 12%; negative in more than 75% of cases
 - CD2 positive in 45%
 - CD43 in 44%
 - CD4 positive in 40%
 - CD8 in 5%
 - CD5 and CD7 negative
 - CD45RO (UCHL-1) variably positive
 - Some cases may have absence of T-cell (or B-cell) lineage referred to as null cell but show evidence of T-cell lineage at genetic level.

Fig. 10-35. Anaplastic large cell (Ki-1+) lymphoma.

A, Nodal involvement showing characteristic infiltrate in nodal sinuses simulating sinus histiocytosis or metastatic neoplasm. **B**, Tumor cells are large with pleomorphic nuclei with an eccentric location and occasional perinuclear eosinophilic region; numerous mitoses including atypical forms are present. **C**, Occasionally may occur in mucosal sites such as this example in a tonsil; immunoreactivity may include **(D)** (*left panel*) CD30 (Ki-1) and (*right panel*) epithelial membrane antigen; **(E)** ALK-1–positive (nuclear and cytoplasmic staining).

- Cytotoxic associated antigens including TIA-1, granzyme B, and/or perforin expressed in most cases (60% to 88%)
 - Clusterin expressed in majority (>90%) of cases showing Golgi staining pattern
 - Leukocyte common antigen (LCA or CD45) variably positive
 - B-cell markers positive in about 10% of cases
 - CD15 may be positive in a small percentage of cases.
 - CD56 expressed in some cases, associated with worse prognosis
 - Epithelial markers including cytokeratin and p63 may be positive:
 - Cytokeratin rarely positive
 - p63 may be positive in up to 41% of cases.
 - S100 protein, melanoma markers, myogenic markers negative
 - EBV negative
 - Cytogenetics and molecular genetics:
 - Clonal rearrangement of T-cell receptor (TCR) genes in approximately 90% of cases:
 - Presence of TCR genes occurs regardless of whether there is or is not immunoreactivity for T-cell markers
 - Translocation of *ALK* gene on chromosome 2p23:
 - Most common form is t(2;5)(p23;35)
 - *ALK* gene normally not expressed on lymphoid cells and all postnatal normal human tissues except rare cells in the brain so immunohistochemical staining has by and large supplanted molecular tests for *ALK* expression
 - Gene expression profiles have shown distinct molecular signatures between ALCL, ALK-positive and ALCL, ALK-negative cases.
 - Cytomorphologic variants of ALCL, ALK+ include:
 - Common variant (described above) representing approximately 70% of cases
 - Lymphohistiocytic variant representing approximately 10% of cases and characterized by neoplastic cells (see above) admixed with histiocytes
 - Small cell variant representing approximately 5% to 10% of cases and characterized by CD30-negative small T-lymphocytes with irregular nuclei and a minor population of CD30-positive larger cells; the latter tend to concentrate around blood vessels:
 - Signet ring-like cells may be seen.
 - May transform to common variant in approximately one-quarter of cases;
- transformation heralds rapid clinical course with patient dying within 1 year
- Hodgkin-like variant representing approximately 3% of cases and characterized by morphologic features mimicking nodular sclerosis classic Hodgkin disease
 - Monomorphic variant characterized by medium-sized to large cells
 - With uniformity of size and shape (i.e., monotonous appearance), although hallmark lesional cells are usually present
 - Other variants include hypocellular, giant cell, and sarcomatoid variants.
 - Mixed cell or composite variant includes admixture of variants detailed above.
 - Treatment includes multiagent chemotherapy with favorable outcome:
 - Overall 5-year survival of 70% to 77% and failure-free survival (FFS) of 60%
 - In contrast, overall 5-year survival of 48% and FFS of 36% reported for ALCL, ALK-negative cases
 - Relapses commonly occur (approximately 30%) but remain sensitive to chemotherapy.
 - Bone marrow reported from 10% to 17% but increased to near 40% when immunostaining for CD30 is performed:
 - Bone marrow involvement associated with worse prognosis
 - Other types of lymphomas that may rarely occur in Waldeyer ring include (although not limited to):
 - Mantle cell lymphoma (MCL)
 - Follicular lymphoma
 - For more complete discussion on lymphomas, the reader is referred to comprehensive texts on hematolymphoid neoplasms.

Plasma Cell Neoplasms

Definition: Result from expansion of a clone of immunoglobulin (IgG)-secreting heavy chain class-switched terminally differentiated B cells that secrete a single homogeneous monoclonal immunoglobulin referred to as a paraprotein or M-protein; presence of such a protein known as monoclonal gammopathy.

- Plasma cell neoplasms include:
 - Plasma cell myeloma (multiple myeloma):
 - Bone marrow based multifocal plasma cell neoplasm associated with M-protein in serum and/or in urine
 - In most cases there is disseminated bone marrow involvement
 - Clinical spectrum may span from asymptomatic to aggressive and disorders due to deposition of abnormal immunoglobulin chains in tissues

- Plasmacytoma:
 - Solitary plasmacytoma of bone
 - Extramedullary (extraosseous) plasmacytoma
- Immunoglobulin deposition disease:
 - Primary amyloidosis
 - Systemic light chain and heavy chain deposition diseases
- Monoclonal gammopathy of undetermined significance (MGUS)
 - Considered a precursor lesion to plasma cell neoplasm in which there is a low level of paraprotein in peripheral blood below the usual threshold for diagnosis of plasma cell myeloma but may precede development of overt myeloma.

Plasmacytoma

Definition: Neoplasm of plasma cells occurring as a solitary lesion or occurring in the setting of multiple myeloma including:

- Solitary plasmacytoma of bone
- Extramedullary plasmacytoma

Solitary Plasmacytoma of Bone (Osseous Plasmacytoma)

Definition: Localized bone tumor consisting of monoclonal plasma cells.

- Most common sites include vertebrae, ribs, skull, pelvis, femur, clavicle, and scapula

Extramedullary Plasmacytoma (EMP) (Fig. 10-36)

Definition: Localized plasma cell neoplasm arising in tissues other than bone.

- 80% occur in the head and neck:
 - Most cases primarily involve the upper aerodigestive tract, including the sinonasal tract and nasopharynx.

Synonym: Extraosseous plasmacytoma

Clinical

- Comprises approximately 3% to 5% of all plasma cell neoplasms
- 80% are primary (solitary) without evidence of tumor elsewhere; 20% are part of the generalized picture associated with multiple myeloma.
- More common in men than women; occurs over a wide age range but the vast majority of patients are over 40 years of age
- Tends to develop in mucosa-associated sites, including the sinonasal tract, nasopharynx, pharynx (including tonsil), larynx, oral cavity, salivary glands, and thyroid gland

- Clinical presentation dependent on the site of occurrence and may include a soft tissue mass, airway obstruction, epistaxis, pain, proptosis, or cranial nerve involvement
- Serum immunoelectrophoresis may show monoclonal abnormalities in both the systemic and localized forms of the disease:
 - Up to 25% of patients have a monoclonal gammopathy (M component).
 - Disappearance of the M component may be indicative of a cure
- Radiologic features include a soft tissue density; bone destruction may be present; in patients with primary EMP, skeletal survey will be negative.

Pathology

Gross

- May appear as a sessile or pedunculated, mucosa-covered mass measuring from 1 to 7.5 cm in greatest dimension
- Soft to rubbery to firm consistency with a variable color
- Bleed easily on biopsy

Histology

- Typically, submucosal lesion with a diffuse growth pattern and replaces the normal tissue parenchyma
- Composed of plasma cells with varying degrees of maturation including mature, immature, and anaplastic
- Mature plasma cells:
 - Round to oval with an eccentrically situated round nucleus
 - Nucleus has a characteristic clock face chromatin pattern but dispersed nuclear chromatin can be seen
 - Characteristic paranuclear clear zone represents the Golgi apparatus where immunoglobulin is processed and glycosylated for secretion
 - Cytoplasm is abundant and basophilic.
- Immature plasma cells:
 - Larger more irregular appearing nuclei, less condensed chromatin and occasional nucleoli
- Anaplastic variant (See Section 1, Sinonasal Tract) characterized by:
 - Cells with enlarged pleomorphic nuclei, indistinct to prominent eosinophilic nucleoli and a variable amount of eosinophilic cytoplasm
 - Tumor giant cells may be present and there is increased mitotic activity, including atypical forms.
 - In these anaplastic types, the cells may have a plasmacytoid appearance but, by and large, there is loss of the histologic features diagnostic of plasma cell tumor.

Fig. 10-36. Extramedullary plasmacytoma of the nasopharynx.

A, Diffuse proliferation of mature plasma cells characterized by round to oval cells with eccentrically situated round nuclei with clock face or dispersed nuclear chromatin, abundant basophilic appearing cytoplasm, and the presence of paranuclear clear zones. **B**, Another example predominantly comprised of immature plasma cells comprised of cells with larger more irregular appearing nuclei, less condensed chromatin, occasional nucleoli, and increased mitotic activity. Lesional cells are immunoreactive for **(C)** CD138, **(D)** MUM1 (nuclear). Neoplastic plasma cells typically show light chain restriction as seen by in situ hybridization showing the **(E)** presence of lambda light chain staining and **(F)** absence of kappa light chain staining.

- Amyloid deposits may be present in association with the plasma cell infiltrate and stain with Congo red or crystal violet
- Immunohistochemistry:
 - Monotypic cytoplasmic immunoglobulin (IgG or IgM type) heavy and/or light chain restriction (by immunohistochemistry or in situ hybridization)
 - Is present plasma cell malignancies generally are:
 - CD79a, CD138, CD38, MUM1, OCT2 and BOB.1 often positive
 - Leukocyte common antigen (CD45) often but not always negative
 - CD20 and PAX 5 negative
 - Variable EMA staining
 - Some cases may be cytokeratin positive
 - CD31 may be positive
 - May express CD56 in majority of cases

Differential Diagnosis

- Reactive plasmacytosis
- IgG4-related disease
- Diffuse large B cell lymphoma:
 - CD45 and CD20 positive in contrast to plasma cell neoplasm that are typically CD45 and CD20 negative and CD138 positive
- Plasmablastic lymphoma:
 - Distinctive aggressive variant of diffuse large B-cell lymphoma often occurring in HIV patients and arising in the oral cavity
 - Share similar histologic features and immunophenotype as plasma cell neoplasms including CD138, MUM1, CD38 positive and CD20 negative
 - Majority of cases associated with Epstein-Barr virus (EBER positive) but not associated with human herpes virus 8 (HHV8)
- Carcinoma:
 - Presence of cytokeratins and/or EMA and absence of CD45 and CD20 may lead to an erroneous diagnosis of an epithelial malignancy

Treatment and Prognosis

- Diagnosis of EMP warrants complete skeletal examination and clinical staging to determine the extent of disease and thus predict the outcome:
 - Staging is required prior to the initiation of therapy and may necessitate a bone marrow biopsy.
- Treatment is dependent on the extent of disease and may include radiotherapy alone or, for large tumors, local resection followed by radiotherapy.
- Many cases of EMP remain localized, and surgical resection with postoperative radiotherapy (30-50 Gy) is curative.
- 70% of patients with EMP are alive at 10 years, with a median survival of 7 to 9 years

- Involvement of a head and neck site may represent dissemination from multiple myeloma, or dissemination may occur to other sites from the primary head and neck involvement.
- Prognosis is drastically affected by the presence of disseminated disease—median survival after dissemination is less than 2 years.

Mucosal Malignant Melanoma

Definition: Neural crest-derived neoplasms originating from melanocytes and demonstrating melanocytic differentiation.

- For a more complete discussion see Section 1, Sinonasal Tract.

Sarcomas

- In general, sarcomas of the pharynx are uncommon.
- Although uncommon, virtually all types of sarcomas may occur in these sites.
- Among the more common sarcomas of the pharynx, in particular the nasopharynx, is rhabdomyosarcoma and synovial sarcoma.

Rhabdomyosarcoma (RMS)

(Figs. 10-37 through 10-42)

Definition: Malignant neoplasm showing skeletal muscle differentiation.

Clinical

- Most common soft tissue sarcoma in children under 15 years of age:
 - Accounts for approximately 3% to 4% of all childhood sarcomas of adolescents and young adults
 - Occurs predominantly in infants and children; less frequent occurrence in adolescents and young adults
 - Approximately 2% occur at birth
 - Annual incidence of 4.5 cases per million per year
- Rare in people older than 45 years:
 - Accounts for approximately 2% to 5% of all adult sarcomas
- Anatomic distribution of RMS includes:
 - Head and neck is the most common site of origin with approximately 35% of all cases.
 - Of these approximately 25% to 33% involve the upper aerodigestive tract.
 - Genitourinary tract second most common site with approximately 24% of all cases
 - Following the head and neck and genitourinary tract, the next most common sites of occurrence

Fig. 10-37. Embryonal rhabdomyosarcoma.

A, At low magnification there is variability in cellularity, including alternating hyper- and hypocellular (myxoid) areas. **B**, The neoplastic infiltrate is composed of small undifferentiated (primitive-appearing) round cells with hyperchromatic nuclei and indistinct cytoplasm; mild nuclear pleomorphism, increased mitotic activity (*arrows*), and individual cell necrosis are present. **C**, Scattered within the malignant small round cell infiltrate are rhabdomyoblasts appearing as large round to oval cells with prominent eosinophilic cytoplasm (*arrowheads*). **D**, The neoplastic infiltrate may include cells with clear-appearing cytoplasm. **E**, PAS staining showing the presence of intracytoplasmic-positive material indicative of glycogen deposition (removed with diastase, not shown); lesional cells are diffusely immunoreactive for (**F**) desmin and (**G**) myogenin (myf-4, nuclear staining).

Continued

Fig. 10-37, cont'd

in decreasing order include extremities (19%), parameningeal (16%), and orbit (9%).

- Approximately 32% occur in “miscellaneous” or “other” sites.
- Histologic type (see below) correlates to patient age:
 - Embryonal RMS, including botryoid and spindle cell subtypes, affect primarily young children between birth and 15 years but is not limited to this age group.
 - Alveolar RMS tends to affect older patients with peak ages of 10 to 25 years, although it may also occur in older adults.
 - In adult populations over 40 years of age, embryonal RMS is the most common histologic type; in addition, spindle cell RMS occurs in a significant percentage of adult RMS.

Head and Neck RMS

- In the head and neck, RMS is primarily but not exclusively a disease of the pediatric population:

Fig. 10-38. Embryonal rhabdomyosarcoma, botryoid type.

A, Polypoid mass protruding into the lumen of the trachea at the carina (*arrow*). **B**, Polypoid nodule with loose myxoid stroma separating the submucosal tumor cells from intact surface epithelium. **C**, Another example showing subepithelial condensation of tumor cells separated from intact surface ciliated respiratory epithelium by a thin layer of hyalinized-appearing stroma. **D**, Neoplastic cells include primitive (undifferentiated) small cells as well as cells with stellate cytoplasmic processes set in a myxoid stroma; Y-shaped plexiform capillary blood vessel is present.

Fig. 10-39. Embryonal rhabdomyosarcoma, spindle cell variant.

A, Spindle cell proliferation arranged in fascicular and storiform growth pattern. **B**, Collagen-rich type characterized by spindle cells separated by abundant collagenized stroma arranged in storiform to whorled growth pattern. **C**, Relatively uniform-appearing spindle-shaped cells. **D**, Scattered rhabdomyoblasts are present. The spindle cells are immunoreactive for **(E)** desmin and **(F)** myogenin (myf-4, nuclear staining).

Fig. 10-40. Alveolar rhabdomyosarcoma.

A, Alveolar rhabdomyosarcoma is characterized by neoplastic aggregates separated by a hyalinized fibroconnective tissue. **B**, In alveolar rhabdomyosarcoma there is often loss of cellular cohesion resulting in “alveolar” spaces; scattered rhabdomyoblasts are present. **C**, Solid form of alveolar rhabdomyosarcoma characterized by densely packed clusters of tumor cells resembling round cell areas of embryonal RMS but an absence of an alveolar growth pattern; lesional cells about a residual submucosal mucoserous gland (*right*). **D**, Multinucleated giant cell with peripherally situated nuclei (*arrowhead*) represent a diagnostically important finding in alveolar rhabdomyosarcoma; in contrast, multinucleated giant cells are not commonly found in embryonal RMS; scattered mitotic figures are present (*arrows*). Lesional cells are immunoreactive for **(E)** desmin and **(F)** myogenin (myf-4, nuclear staining).

Fig. 10-41. Pleomorphic rhabdomyosarcoma.

Pleomorphic rhabdomyosarcoma characterized by large round or pleomorphic tumor cells with hyperchromatic nuclei, prominent nucleoli, and eosinophilic cytoplasm; spindle-shaped or racket-shaped cells (rhabdomyoblasts) with irregular contours are present; an atypical mitotic figure can be seen (*arrow*).

- 43% of patients are under 5 years of age
- 78% of patients are under 12 years of age
- In the head and neck, parameningeal tumors are the most common and include:
 - Nasopharynx, sinonasal tract, middle ear and mastoid, pterygopalatine-infratemporal fossa
- Most frequent sites in the head in neck include:
 - Nasopharynx > middle ear and mastoid > sinonasal tract > soft tissues of the neck > oral cavity (tongue, lip, palate)
- In children and adolescents, RMS represents the most common aural-related malignant neoplasm.
- No gender predilection, although some reports show a slight male predominance
- Symptoms depend on the site of occurrence but due to destructive growth include:
 - Pain, facial swelling, bleeding, proptosis, airway obstruction, and difficulty breathing
 - At diagnosis approximately one third of patients have associated neurologic findings, the most common of which are facial nerve deficits; neuropathies of cranial nerves III, V, VI-XII may also occur.
 - Middle ear and mastoid may present with painless unilateral otitis media unresponsive to antibiotic therapy associated with a serosanguineous discharge.
- Cause:
 - Majority of RMS occurs with no known etiologic factors.
 - Small subset occurs with syndromes caused by germline mutations:
 - Embryonal RMS associated with syndromes caused by mutations in the RAS signaling

BOX 10-4 Modified Conventional Classification of RMS*

- Embryonal
- Botryoid
- Alveolar
- Pleomorphic
- Sarcoma not classified
- Small round cell sarcoma, type indeterminate
- Extrasosseous Ewing sarcoma

*Horn and Enterline Classification.
RMS, Rhabdomyosarcoma.

BOX 10-5 National Cancer Institute Classification of RMS

Embryonal RMS (Favorable)

- Conventional
- Botryoid
- Leiomyomatous
- Aggressive histologic features

Alveolar RMS (Unfavorable)

- Conventional
- Solid

Pleomorphic RMS

RMS (other)

RMS, Rhabdomyosarcoma.

pathway including Costello syndrome (*HRAS* gene mutations), neurofibromatosis 1 (*NF1* gene mutations), and Noonan syndrome

- Some embryonal RMSs are associated with Beckwith-Weidemann syndrome (dysregulation of imprinted genes in 11p15.5 region).
- RMS of unclassified histology occurs in Li-Fraumeni syndrome (caused by *TP53* mutations) and infrequently (as well as embryonal RMS) in Gorlin syndrome (*PTCH1* mutations in active hedgehog signaling pathway)

Pathology

Gross

- RMS of mucosal sites of the upper aerodigestive tract appears as submucosal, well-circumscribed, multinodular, or polypoid lesions that on cut section has a glistening, gelatinous, gray-white surface; hemorrhage and cyst formation may be seen.
- RMS of the middle ear and mastoid most often appears as an aural (external or middle ear) polypoid lesion similar in appearance to an aural polyp.

Histology

- Histologic classification of RMS has evolved over time (Boxes 10-4 through 10-6); at present the

Fig. 10-42. Sclerosing rhabdomyosarcoma.

A, Neoplastic cells with associated abundant eosinophilic hyalinized stroma are composed of primitive-appearing nuclei with coarse nuclear chromatin and irregular nuclear contours. **B,** Eosinophilic hyalinized stroma is a dominant feature; increased mitotic activity is present (*arrowheads*). **C,** Strong desmin reactivity. **D,** Very focal myogenin (*myf-4*) staining including one positive cell with identifiable cross-striations (*arrow*).

BOX 10-6 International Classification of RMS

Superior Prognosis

- Botryoid RMS
- Spindle RMS

Intermediate Prognosis

- Embryonal RMS

Poor Prognosis

- Alveolar RMS
- Undifferentiated RMS

Subtypes Whose Prognosis Is Not Presently Evaluable

- RMS with rhabdoid features

RMS, Rhabdomyosarcoma.

International Classification of RMS, a modification of the conventional scheme, is advocated given its reproducibility and prognostic significance (see [Box 10-6](#)).

- Majority of head and neck RMS of all ages and all sites is embryonal type that includes botryoid and spindle cell subtypes.
- Next most common histologic type is alveolar RMS; alveolar RMS tend to occur in older aged individuals as compared with embryonal RMS, including botryoid and spindle subtypes.
- Other histologic types of RMSs may occur in the head and neck but are considered uncommon.
- Rhabdomyoblasts, the cell of origin for this sarcoma, take on numerous appearances, including small round cells to ribbon- or strap-shaped to large and pleomorphic:

- Rhabdomyoblasts with cross-striations are not always identified, and their absence does not exclude the diagnosis of rhabdomyosarcoma.

Embryonal RMS (see Fig. 10-37)

- Typically, at low magnification there is a variation in the cellularity of these tumors with alternating hyper- and hypocellular areas; the latter often is associated with a loosely textured myxoid stroma.
- Composed of primitive mesenchymal cells in various stages of embryogenesis of normal skeletal muscle (myogenesis), ranging from well-differentiated neoplasms resembling skeletal muscle to poorly differentiated neoplasms requiring immunohistochemical staining to confirm myogenic differentiation
- Cellular components consist of an admixture of cell types, including:
 - Small undifferentiated (primitive-appearing) round or spindle-shaped cells with hyperchromatic nuclei and indistinct cytoplasm; mild nuclear pleomorphism, increased mitotic activity, and necrosis are present
 - Differentiated large round to oval cells with eosinophilic cytoplasm characteristic of rhabdomyoblasts
 - Matrix with little collagen and varying amounts of myxoid stroma
- Cells with cross-striations are rare in round cells but are more apparent neoplasms with more prominent spindle cell component and can be seen in 50% to 60% of cases:
 - Rhabdomyoblasts range from slender spindle-shaped cells with peripherally placed myofibrils to large eosinophilic cells with strap, tadpole, ribbon, or racket shapes and one or two centrally positioned nuclei and prominent nucleoli with or without cross-striations.
 - As compared with the cross-striations of normal skeletal muscle, the cross-striations in rhabdomyoblasts are more irregular in distribution and traverse only part of the cell.
- Uncommonly, embryonal RMS with foci of prominent cellular pleomorphism may occur; these tumors are still recognized as embryonal RMS given:
 - Presence of areas of more typical embryonal RMS
 - Frequent identification of cross-striations
 - Prognosis not altered except if the cellular pleomorphism is diffuse, at which point differentiation from pleomorphic RMS is difficult.
- Heterologous elements, including (immature) cartilage and/or bone may be identified:
 - These findings are more often seen in RMS of the genitourinary tract and in retroperitoneal RMS.

Botryoid Variant of Embryonal RMS (Sarcoma Botryoides) (see Fig. 10-38)

- Terminology derived from Greek term *botryos*, meaning bunch of grapes
- Gross appearance in a hollow viscus or body cavity is as a polypoid mass:
 - Characteristic gross appearance not required for diagnosis
- Histologically, subepithelial condensation of tumor cells separated from intact surface epithelium by a zone of loose stroma referred to as a cambium layer:
 - Cambium layer represents required criteria for diagnosis of botryoid type
 - Surface epithelium may show reactive hyperplasia or metaplasia (e.g., squamous cells).
- Polypoid nodules often with loose myxoid stroma
- Cells range from primitive (undifferentiated) small cells to cells with rhabdomyoblastic differentiation:
 - Cells with stellate cytoplasmic processes are often prominent.
- Stroma typically loosely cellular with myxoid appearance

Spindle Cell RMS (see Fig. 10-39)

- Rare subtype that tends to occur in young patients (less than 7 years of age) with a male predilection
- Most frequently found in the paratesticular region but second most common site of occurrence includes mucosal sites of the head and neck, including nasopharynx and sinonasal tract.
- Grossly, appears well circumscribed but unencapsulated with a nodular, whorled appearance on cut section and measuring from 4 to 6 cm in greatest diameter
- Histology:
 - Composed almost exclusively of elongated fusiform or spindle cells with cigar-shaped or blunted central nuclei and tapered ends (similar to smooth muscle cells) and prominent nucleoli
 - Cells have eosinophilic fibrillar cytoplasm with distinct cell borders with or without identifiable cross-striations (pointing to skeletal muscle differentiation).
 - Collagen-rich type characterized by spindle cells separated by abundant collagenized stroma arranged in storiform to whorled growth pattern
 - Collagen form type more cellular proliferation with cells arranged in bundles or fascicles (resembling fibrosarcoma)

Alveolar RMS (see Fig. 10-40)

- Composed of ill-defined aggregates of poorly differentiated small round to oval neoplastic cells with

central loss of cellular cohesion resulting in formation of irregular alveolar spaces

- Dense, hyalinized fibroconnective and/or fibrovascular septa surround and separate the neoplastic aggregates.
- Tumor cells have round to oval hyperchromatic nuclei with a scant amount of indistinct cytoplasm:
 - Cells at the center of the alveolar spaces are more loosely arranged and often show degenerative changes as well as necrosis.
 - Cells at the periphery of the alveolar spaces are better preserved and often adhere to the fibrous septa.
 - Mitotic figures are readily identified.

Solid Form of Alveolar RMS

(see Fig. 10-40)

- Absence of an alveolar pattern and the neoplasm is composed of densely packed clusters of tumor cells resembling round cell areas of embryonal RMS but with more uniform cellularity with little to no fibrosis
- Solid areas more commonly seen at periphery of the tumor
- Often incipient alveolar spaces are present.
- Similar to examples with alveolar pattern, in the solid form there is:
 - Regular arrangement of fibrous septa surrounding primitive round cells
 - Tumor cells with round to oval hyperchromatic nuclei with a scant amount of indistinct cytoplasm
 - Increased mitotic activity
- Neoplastic rhabdomyoblasts with prominent granular eosinophilic cytoplasm are less common in the alveolar type than in the embryonal type:
 - Rhabdomyoblasts in alveolar RMS located or attached to fibrous septa tend to be strap- or spindle-shaped.
 - Cross-striations are not commonly identified and, if present, are found in spindle-shaped or strap cells.
- Multinucleated giant cells are often found in alveolar RMS and represent a diagnostically important finding:
 - In contrast, multinucleated giant cells are not commonly found in embryonal RMS.
 - Giant cells typically have multiple peripherally situated nuclei with weakly eosinophilic cytoplasm and absence of cross-striations.
- Lymph node metastasis may precede identification of primary tumor:
 - When alveolar RMS metastasizes, the alveolar pattern may be retained in the metastatic site.

Pleomorphic RMS (see Fig. 10-41)

- Rare high-grade variant of RMS occurring almost exclusively in adults older than 45 years (mean of 56 years), although may occur in younger patients (second and third decades of life)
- Predilection to males
- Most common site of occurrence is the deep soft tissues of extremities, in particular the thigh; less common sites of occurrence include the chest wall, abdomen/retroperitoneum, chest/abdominal wall, spermatic cord/testes, upper extremity, and head and neck.
- Typically present as rapidly enlarging, painless mass growing over months; metastatic disease (to lungs) may occur at presentation
- Tumors are usually large, measuring over 10 cm in size.
- Histology is characterized by the presence of loosely arranged, large round or pleomorphic tumor cells with hyperchromatic nuclei and deeply eosinophilic cytoplasm:
 - Pleomorphic, bizarre cells with deeply eosinophilic cytoplasm and some cell-to-cell molding represent the most helpful light microscopic feature in suggesting a diagnosis of RMS.
 - Spindle-shaped, tadpole-shaped, or racket-shaped rhabdomyoblasts similar to those seen in embryonal RMS are present but tend to be larger with more irregular contours.
 - Cells with cross-striations are rare.
 - Cellular proliferation usually is haphazardly arrayed, but storiform and fascicular growth patterns can be present.
- Rarely, cells with rhabdoid morphology can be seen characterized by cells with peripherally placed vesicular nuclei, prominent nucleoli, and intracytoplasmic hyaline inclusions.
- In the presence of primitive round cells, a diagnosis of pleomorphic RMS is questionable and more likely represents alveolar RMS.

Sclerosing RMS (see Fig. 10-42)

- Uncommon variant of RMS characterized by presence of hyalinizing, matrix-rich stroma
- Exact relationship between sclerosing RMS and embryonal RMS or alveolar RMS remains to be determined:
 - Some authors classify sclerosing RMS with spindle RMS, suggesting it is a variant of embryonal RMS.
 - Alternatively, it could be a new subtype of RMS.
- Sclerosing RMS shares some overlapping features with alveolar RMS but does not harbor *PAX 3* fusions as seen in alveolar RMS except for rare single case with a *PAX3-FOXO1A* fusion.

- May occur in children or adults
- Histology:
 - Neoplastic cells divided into lobules, small nests, microalveoli, and single-files with associated abundant hyalinized, eosinophilic to basophilic matrix resembling osteoid or chondroid material
 - Hyalinized stroma is dominant feature that makes up 50% of the entire neoplasm.
 - Moderately cellular lesions composed of primitive-appearing nuclei with coarse nuclear chromatin, irregular nuclear contours, small and occasionally multiple nucleoli, and limited amount of eosinophilic cytoplasm
 - Strap cells may be seen but rhabdomyoblasts are uncommon.
 - High mitotic rate

Epithelioid RMS

- Rare and unusual type of RMS composed of sheets of epithelioid cells with abundant amphophilic to eosinophilic cytoplasm
- Tendency to:
 - Occur in elderly patients (median age of 70 years), male predilection
 - Arise in deep soft tissues of upper and lower extremities, head and neck, and trunk
 - Mimics carcinoma or melanoma
 - Aggressive clinical course
- Histology:
 - Epithelioid cells with large vesicular nuclei, prominent nucleoli, abundant densely eosinophilic cytoplasm
 - High mitotic rate with atypical mitoses

Special Studies

- In the presence of a poorly differentiated neoplasm lacking evidence of cross-striations, special stains are invaluable in confirming the diagnosis of rhabdomyosarcoma and differentiating it from other lesions.
- Histochemistry:
 - Cells contain glycogen as demonstrated by periodic acid-Schiff (PAS) positivity cleared by diastase digestion
 - Intracellular myofibrils can be seen by Masson trichrome and phosphotungstic acid hematoxylin (PTAH) stains.
- Immunohistochemistry:
 - Desmin, myoglobin, myogenic transcription factors (MyoD1, myogenin [myf-4]), and muscle-specific actin positive:
 - Desmin not entirely specific but is reasonably sensitive marker for RMS:
 - Can be seen in a wide variety of lesions including although not limited to leiomyosarcoma, epithelial neoplasms, others

- Cytoplasmic staining
- In sclerosing RMS shows dot-like staining which is unique and different staining pattern as seen in other types of RMSs
- Myoglobin is a specific although not sensitive marker for skeletal muscle tumors:
 - Tends to be restricted to more differentiated cells
 - Can be detected in non-muscle cells due to diffusion
 - Cytoplasmic staining
- Myogenic transcription factors (MyoD1, myogenin [myf-4]):
 - Expressed in more than 90% of RMSs of all subtypes
 - Excellent specificity but may be seen in other rare tumor types with rhabdomyoblastic differentiation
 - Nuclear staining
 - MyoD1 and myogenin expressed in >95% of embryonal cells including spindle cell RMS and alveolar RMS including solid variant
 - Embryonal RMS expresses very high levels of MyoD1 and comparatively less MyoD1 or equal expression of both
 - Alveolar RMS expresses very high levels of myogenin and comparatively less MyoD1
 - Sclerosing RMS typically shows strong expression of MyoD1 but very little myogenin (myf-4).
 - Pleomorphic RMS less frequently MyoD1 and myogenin positive, and may only show small percentage of positive tumor cells
- Muscle-specific actin-sensitive marker for RMS but:
 - Can be seen in a wide variety of lesions including although not limited to leiomyosarcoma, epithelial neoplasms, others
 - May be absent in poorly differentiated RMS
 - Cytoplasmic staining
- Cytokeratins, S100 protein, leukocyte common antigen, neuroendocrine markers (chromogranin, synaptophysin, CD56), and melanocytic markers are typically negative:
 - Cytokeratins including wide spectrum and CAM5.2 may be identified in alveolar RMS in up to 50% of cases
 - Neuroendocrine markers may be positive in alveolar RMS, including CD56 (present in majority of cells), synaptophysin (up to about one third of cases), and chromogranin (up to about 22% of cases)
 - CD99 may be present in alveolar RMS.

- Ultrastructural findings:
 - Bundles of thick (myosin) filaments with attached ribosomes (ribosome and myosin complex) and thin (actin) fibrils
 - Admixture of alternating thin (actin) and thick (myosin) filaments in parallel (longitudinal) arrangement with hexagonally appearing (on cross section) Z banding
 - Golgi apparatus, mitochondria, glycogen droplets can be present.
 - Cytogenetic and molecular genetics:
 - Embryonal RMS:
 - Consistent loss of heterozygosity (LOH) at chromosome 11p15.5, which may result in activation of tumor suppressor gene(s) GOK
 - Botryoid type:
 - Deletion of short arm of chromosome 1
 - Trisomies of chromosomes 13 and 18
 - Hyperdiploid clone with complex karyotype including numerous chromosomal gains
 - Case with trisomy 8
 - Spindle cell RMS:
 - Very few reports on cytogenetics, including:
 - Absence of PAX3-FOXO1 or PAX7-FOXO1 gene fusion:
 - ◻ Genetically more closely related to embryonal RMS than alveolar RMS
 - Der(2)t(2;7) with involvement of 2q36-37
 - Structural rearrangements of chromosomes 8, 12, 21, 22
 - NCOA2 rearrangements found in pediatric but not adult cases, suggesting:
 - ◻ Spindle cell RMS is a heterogeneous disease genetically as well as clinically
 - ◻ A relationship between NCOA2-rearranged spindle cell RMS occurring in young childhood and congenital RMS, which often displays rearrangements at 8q13 locus (NCOA2)
 - Alveolar RMS characterized by distinctive cytogenetic abnormalities distinct from other types of RMSs and other round cell tumors:
 - t(2;13)(q36;q14) translocation 60% of cases:
 - Above translocation results in shortening of chromosome 13 and elongation of chromosome 2:
 - ◻ Breakpoints occur in PAX3 gene at chromosome 2 and FOXO1A gene (formerly FKHR) on chromosome 13 results in a PAX3-FOXO1A fusion gene on chromosome 13 and a FOXO1A-PAX3 fusion gene on chromosome 2.
 - ◻ PAX3-FOXO1A fusion appears to be more sensitive and specific than FOXO1A-PAX3 in detecting RMS.
 - t(1;13)(p36;q14) translocation in 20% of cases
 - Juxtaposes PAX7 gene on 1p36 with FOXO1A gene on 13q14
 - Approximately 80% of alveolar RMS have PAX3-FOXO1A fusion or PAX7-FOXO1A fusion; therefore approximately 20% lack either of these fusions:
 - About half of the fusion-negative cases had solid growth pattern.
 - None of the PAX3-FOXO1A fusion had solid growth pattern.
 - Rare examples with PAX7-FOXO1A fusion had solid growth pattern.
 - Gene expression microarray data indicate that several genes discriminate between fusion-positive and fusion-negative RMS with high specificity:
 - A panel of immunohistochemical markers, including myogenin, AP2β, NOS-1, and HMGA2 can be used as surrogate markers of fusion status in RMS:
 - ◻ Provide an alternative to molecular methods for identification of fusion-positive RMS
 - ◻ Useful in cases with scant or poor-quality material; useful in fusion-negative alveolar RMS as an indicator that a variant gene fusion may be present
 - Fibroblast growth factor receptor genes FGFR4 and FGFR1 recently implicated in pathogenesis of alveolar RMS
- Sclerosing RMS:
 - Do not harbor PAX 3 fusions as seen in alveolar RMS, except for rare single case with a PAX3-FOXO1A fusion.

Differential Diagnosis

- Aural polyp:
 - Embryonal RMS of the middle ear is frequently polypoid and may be confused with an aural polyp
 - Prominent inflammatory cell infiltrate including mature plasma cells and lymphocytes seen in aural polyps may overrun and obscure diagnostic rhabdomyoblasts.
 - Cellular components of RMS including spindle-shaped cells with brightly eosinophilic cytoplasm, cross-striations, and immunohistochemical evidence of myogenic marker reactivity contrast with the mixed acute and chronic inflammatory cell infiltrate, including mature plasma cells with Russell bodies seen in aural polyps.
- Poorly differentiated and spindle cell malignant neoplasms, including malignant melanoma, Ewing family of tumors, non-Hodgkin malignant lymphoma, synovial sarcoma, others:

- Differentiation can be accomplished by histochemical, immunohistochemical, and cytogenetic analysis.
- Fetal (juvenile) rhabdomyoma, intermediate type:
 - May be difficult to differentiate from spindle cell RMS
 - Features that may assist in this differential diagnosis include:
 - Greater uniformity and less cellular pleomorphism in fetal rhabdomyoma than in spindle RMS
 - Absence of invasive growth, necrosis, and absent to few mitoses in fetal rhabdomyoma
 - Tendency of fetal rhabdomyoma to occur in older aged individuals as compared with spindle RMS, which often occurs in very young patients (5 years and younger)
- Undifferentiated pleomorphic sarcoma and pleomorphic leiomyosarcoma:
 - May be difficult to differentiate from pleomorphic RMS
 - Differentiation is best accomplished by immunohistochemical staining for myoglobin, MyoD1, or myogenin and by ultrastructural analysis
 - Undifferentiated pleomorphic sarcoma and pleomorphic leiomyosarcoma may show immunoreactivity for actin and desmin.

Treatment and Prognosis

- For all histologic types of RMSs, treatment includes a combination of surgery and multiagent chemotherapy with or without radiotherapy.
- Following biopsy diagnosis, recommendations for treatment depend on several factors including site of the disease, clinical group of the disease, and stage of the disease.
- Tumor staging is an important element in the overall approach to treating the disease; since there is a tendency to bone marrow metastasis, a bone marrow aspiration/biopsy is part of the staging process.
- Clinical staging of patients determined by IRS-II study for patients younger than 21 years with confirmed diagnosis of RMS—[Box 10-7](#)
- TNM classification, [Table 10-9](#); this classification relies on pretreatment assessment of the extent of tumor.
- Favorable and unfavorable factors are detailed in [Box 10-8](#):
 - Low-risk patients include those with localized disease with embryonal histology:
 - Most of these patients have resected Group I and II tumors as well as Group III tumors arising in favorable sites.
 - Intermediate-risk patients include those with embryonal RMS that are Group III, stage II or

BOX 10-7 RMS: Clinical Staging*

Group 1

Localized disease, completely resected (regional nodes not involved)

- A. Confined to muscle or site/organ of origin, completely resected
- B. Contiguous involvement with infiltration outside the muscle or organ of origin. As through fascial planes, completely resected.

Group 2

- A. Gross resection with evidence of microscopic local residual disease
- B. Regional disease with involved lymph nodes, completely resected with no microscopic residual disease
- C. Regional disease with involved nodes, grossly resected, but with evidence of microscopic local and/or nodal residual disease

Group 3

Incomplete resection or biopsy with gross residual disease

Group 4

Distant metastatic disease at presentation

*Intergroup Rhabdomyosarcoma Studies Classification. RMS, Rhabdomyosarcoma.

BOX 10-8 RMS: Favorable and Unfavorable Factors

Prognostically Favorable

- Infants and children
- Orbital or genitourinary (non-bladder or prostate) location
- Small size (<5 cm)
- Botryoid or spindle cell type
- Localized noninvasive tumor without regional lymph node involvement or distant metastasis
- Complete initial resection

Prognostically Unfavorable

- Adults
- Location in head and neck (nonorbital), paraspinal region, abdomen, biliary tract, retroperitoneum, perineum, or extremities
- Large size (greater than 5 cm)
- Alveolar (especially *PAX3/FOXO1A* fusion transcript positive) or pleomorphic type
- Diploid DNA content
- Local tumor invasion, especially parameningeal or paraspinal region, paranasal sinuses, or skeleton
- Local recurrence whether during or not during therapy
- Regional lymph node involvement or distant metastasis
- Incomplete initial excision or unresectability
- Diffuse myogenin expression

RMS, Rhabdomyosarcoma.

III, and all patients with nonmetastatic alveolar RMS.

- High-risk patients include all those with metastatic disease.
- Prognostic gene-expression signature reported with reproducible and significant effects:
 - Among nonmetastatic patients, patients who were *PAX3/FOXO1* positive had significantly

TABLE 10-9 Rhabdomyosarcoma: TNM Staging*

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor 5 cm or less in greatest dimension
T1a	Superficial tumor*
T1b	Deep tumor*
T2	Tumor >5 cm in greatest dimension
T2a	Superficial tumor*
T2b	Deep tumor*
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1 [†]	Regional lymph node metastasis
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis
Anatomic Stage/Prognostic Groups	
Stage IA	T1a N0 M0 G1,GX T1b N0 M0 G1,GX
Stage IB	T2a N0 M0 G1,GX T2b N0 M0 G1,GX
Stage IIA	T1a N0 M0 G2,G3 T1b N0 M0 G2,G3
Stage IIB	T2a N0 M0 G2 T2b N0 M0 G2
Stage III	T2a,2b N0 M0 G3 Any T N1 M0 Any G
Stage IV	Any T Any N M1 Any G
Histologic Grade (G) (FNCLCC System preferred)	
GX	Grade cannot be assessed
G1	Grade 1
G2	Grade 2
G3	Grade 3

Used with permission from Edge et al: AJCC cancer manual, ed 7, New York, 2010, Springer-Verlag, p 297.

*Superficial tumor is located exclusively above the superficial fascia without invasion of the fascia; deep tumor is located either exclusively beneath the superficial fascia, superficial to the fascia with invasion of or through the fascia, or both superficial yet beneath the fascia.

[†]Presence of positive nodes (N1) in M0 tumors is considered Stage III.

Grade is determined by differentiation, mitotic activity, and extent of necrosis. Each parameter is scored as: differentiation 1-3; mitotic activity 1-3; necrosis 0-2. Scores are summed to designate grade including: G1 = 2 or 3; G2 = 4 or 5; G3 = 6-8.

Differentiation: Score 1 = sarcoma resembling normal, mature mesenchymal tissue; Score 2 = sarcomas of definite histologic type; Score 3 = synovial sarcomas, embryonal sarcomas, undifferentiated sarcomas, sarcomas of unknown/doubtful tumor type.

Mitotic account: Score 1 = 0-9 mitoses per 10 high power fields (HPFs); Score 2 = 10-19 mitoses per 10 HPFs; Score 3 = > 20 mitoses per 10 HPFs.

Necrosis: Score 1 = no tumor necrosis; Score 2 = ≤ 50% tumor necrosis; Score 3 = >50% tumor necrosis.

poorer outcome compared with alveolar-negative and PAX7/FOXO1-positive patients.

- Overall survival rates based on data from IRS-IV includes:
 - 95% for low-risk patients
 - 75% for intermediate-risk patients
 - 27% for high-risk patients
- Prognosis is best for orbital RMS followed by head and neck and genitourinary (nonbladder/prostate) RMS:
 - 5-year survival rates include:
 - Orbit: 92%
 - Head and neck, nonprostate/bladder RMS: 80%
 - Parameningeal, bladder, prostate, extremities: 70%
- Poorest prognosis seen in association with RMS of retroperitoneum, biliary tract, and peritoneum
- Adverse outcomes accounting for prognostic differences related to anatomic sites have been linked to:
 - Late detection of tumor
 - Large tumor size
 - Difficulties during surgical excision
 - Meningeal involvement with or without spinal fluid spread
 - Metastatic disease
- Diffuse immunohistochemical reactivity for myogenin correlated with decreased recurrence-free intervals and overall survival independent of histologic subtype, translocation status, tumor site, or stage
- A problem specifically related to middle ear and mastoid RMS is the delay in diagnosis due to misinterpretation of the biopsy specimen as inflammatory polyps or as granulation tissue; this delay in diagnosis may result in more advanced stage disease, placing patients at greater risk for treatment failure due to uncontrollable local disease.
- Therapy-induced cytodifferentiation more often seen in embryonal RMS, including botryoid subtypes as compared with other subtypes:
 - In botryoid RMS, cytodifferentiation and decreased proliferative activity are associated with favorable clinical course.
- High recurrence rate seen in association with inadequately resected tumors:
 - Recurrent tumor may herald metastatic disease.
 - Histology of recurrent RMS may be less differentiated than primary RMS, although some may show greater degree of differentiation (e.g., rhabdomyoblasts with cross-striations) than primary RMS.
- Metastatic disease occurs in up to 20% of cases; metastatic sites include:
 - Regional lymph nodes: depend on tumor location with greater incidence of nodal metastasis in

patients with RMS of the prostate, paratesticular region, and extremities as compared with RMS of the orbit, head, and neck

- Distant hematogenous metastasis to the lungs, bone marrow > other viscera (brain, meninges, liver, kidney, pancreas, and heart)
- In alveolar RMS, lymph node metastasis may precede identification of primary tumor.
- There may be a high incidence of cardiac metastasis.
- In some examples, cutaneous metastatic disease may be the initial presentation.
- Histology of metastatic RMS may be less differentiated than primary RMS, although some may show greater degree of differentiation (e.g., rhabdomyoblasts with cross-striations) than primary RMS.

Synovial Sarcoma

(Figs. 10-43 through 10-45)

Definition: Malignant soft tissue neoplasm of uncertain histogenesis primarily arising in para-articular regions in close association with tendon sheaths, bursa, and joint capsules but uncommonly occurs within joint spaces displaying a variable degree of epithelial differentiation and specific chromosomal translocation $t(x;18)(p11;q11)$ leading to formation of a *SS18-SSX* fusion gene.

NOTE:

- Despite its designation, origin from synovial tissues has never been confirmed.
- Felt to arise from a pluripotential mesenchymal cell, accounting for its occurrence in unusual locations and expression of epithelial and mesenchymal markers.

Fig. 10-43. Hypopharyngeal synovial sarcoma.

The resected tumor is circumscribed and multinodular with a gray to tan-white appearance.

Synonyms: Synovioma; tenosynovial sarcoma; synovial cell sarcoma; synoviosarcoma; malignant synovioma; synovioblastic sarcoma; soft tissue carcinoma

Clinical

Synovial Sarcoma of Soft Tissues

- Synovial sarcoma represents approximately 5% to 10% of all soft tissue sarcomas.
- Slight male predilection; most often occurs adolescents and young adults in the second through fourth decades of life
- Presentation is that of a palpable, deep-seated swelling or mass often (50% of cases) associated with tenderness and/or pain.
- Predominantly (85% to 95%) occur in the deep soft tissue of the extremities, especially in the vicinity of large joints such as the knee:
 - Intimately related to tendons, tendon sheaths, and bursal structures outside the confines of the joint space
 - Less frequently attached to fascial structures, ligaments, aponeuroses, and interosseous membranes
 - Rarely (less than 5%) are intraarticular; intraarticular involvement more often occurs secondarily by direct extension from an extraarticular lesion
 - Approximately 5% to 10% arise in the head and neck.
 - Approximately 5% arise in the trunk.
 - Remainder occur in a wide variety of unusual sites throughout the body
- Although a specific cause is not known, some cases may have:
 - Antecedent history of trauma to the affected site
 - Prior history of radiation to the affected site

Head and Neck Synovial Sarcoma

- Less than 10% of all synovial sarcomas occur in the head and neck region.
- Equal to slight male predilection; may occur over a wide age range but tends to occur in the adolescent and young adult population with an average age of 25 at the time of presentation.
- Most common sites of occurrence in the head and neck include the neck and the pharyngeal region (hypopharynx and retropharynx):
 - In the neck, synovial sarcoma typically (but not always) localizes to the level of the bifurcation of the carotid artery intimately associated with the prevertebral fascia.
 - Less common site of the occurrence includes the larynx:
 - Laryngeal and hypopharyngeal involvement may occur by direct extension from a neck primary tumor.

Fig. 10-44. Pharyngeal synovial sarcoma.

A through **C**, Biphasic synovial sarcoma comprised of a combination of epithelioid cells and spindle cells with the epithelioid cells lining the gland-like spaces appearing columnar and the spindle-shaped cells arrayed in fascicular to storiform growth pattern. Immunoreactivity in biphasic synovial sarcomas may include (**D**) cytokeratin (AE1/AE3) in the epithelioid cells; (**E**) CK7 in both epithelioid and spindle cells; (**F**) epithelial membrane antigen (EMA) in epithelioid and spindle cells;

Fig. 10-44, cont'd

(**G**) bcl2 in epithelioid and spindle cells; (**H**) CD99 (Ewing's marker) in epithelioid and spindle cells; and (**I**) TLE1 (nuclear staining) in epithelioid and spindle cells, representing an extremely useful marker for synovial sarcoma and serving as a discriminating stain from other sarcomas.

- Rare head and neck sites of occurrence include the oral cavity (tongue, soft palate), tonsil, parotid gland, and trachea.
- Symptoms vary according to site of occurrence:
 - Neck: palpable mass with or without associated pain, weight loss
 - Pharynx (retropharynx, hypopharynx): dysphagia, dyspnea, hemoptysis, otalgia, foreign body sensation in throat, pain, weight loss
 - Larynx: hoarseness, dysphagia, dyspnea, sore throat, foreign body sensation in throat, pain
- Radiology
 - CT and MRI:
 - Heterogeneous soft tissue mass with enhancement
 - Multiple spotty opacifications more pronounced at the periphery than the center of

the lesion in an otherwise undistinguished soft tissue mass is a characteristic finding in about one third of cases; these opacifications represent focal calcifications and, although not limited to synovial sarcoma, may assist in the radiographic differential diagnosis.

- There are no known risk factors.

Pathology

Gross

- Circumscribed or pseudoencapsulated spherical, lobulated, or multinodular mass ranging in size from 1 to 10 cm
- Variation in color (yellow, gray, or white), consistency (soft, rubbery, firm, gritty), and appearance of the cut surface (fibrous, whorled, cystic, mucoid)

Fig. 10-45. Hypopharyngeal monophasic (fibrous) synovial sarcoma.

A, Fascicular to storiform growth. **B**, Stromal calcifications are present (*left lower*). **C**, Fibroblast-like cells composed of well-oriented, plump spindle-shaped cells with oval to spindle-shaped, hyperchromatic to vesicular nuclei and scant, indistinct cytoplasm; stromal hyalinization characterized by thick collagen bands is present (*upper right*). **D**, Diffuse and strong TLE1 (nuclear staining).

Histology

NOTE: Regardless of its site of occurrence, the histologic findings are essentially similar.

- Two major categories of synovial sarcomas including biphasic and monophasic types that are composed of epithelial cells and/or spindle cells:
 - Depending on the relative prominence of cell type and differentiation, synovial sarcomas can be classified into four types:
 - Biphasic: admixture of epithelioid and spindle (fibrous) cells
 - Monophasic fibrous: most common histologic subtype
 - Monophasic epithelioid
 - Poorly differentiated

Biphasic Synovial Sarcoma (Fig. 10-44)

- Classic type consisting of a combination of epithelial cells and spindle cells
- Epithelial cells:
 - Columnar, cuboidal, or polygonal cells
 - Large, round to oval, vesicular nuclei, abundant pale-staining cytoplasm with distinct cell borders
 - Arranged in solid cords, nests, whorls, and glandular structures, the latter containing granular or homogeneous eosinophilic secretions:
 - Squamous metaplasia including keratin pearls and keratohyaline granules may be present and should not be mistaken for squamous cell carcinoma.

- Spindle cells:
 - Generally represent the more prominent component
 - Fibroblast-like composed of well-oriented, plump spindle-shaped cells with oval to spindle-shaped, hyperchromatic to vesicular nuclei and scant, indistinct cytoplasm
 - Form solid sheets resembling fibrosarcoma but typically lack herringbone pattern or long sweeping fascicles seen in fibrosarcoma
- Mitoses in the epithelioid and spindle cell areas can be seen but generally are not abundant.
- Nuclear palisading may occasionally be present; papillary epithelial foci may be present.
- Alternating cellular and less cellular areas are a common finding:
 - Less cellular areas display hyalinization, calcification, or myxoid change.
 - Collagen in hyalinized areas may be diffusely distributed as thick collagen bands separating malignant spindle cells or extensively distributed compressing neoplastic cells to areas with limited hyalinization appearing as narrow bands or plaque-like masses.
 - Myxoid foci tend to be limited but occasionally may be predominantly myxoid.
- Calcification is a characteristic feature:
 - Present in approximately 20% of cases
 - Varies in any given case from focal and irregular in distribution to extensive and readily identified
 - More pronounced at the periphery of tumor than at its center
 - May or may not be associated with ossification; chondroid foci are rare
- Some examples may show prominent cystic change.
- Mast cells often are present and tend to be more numerous in the spindle cell areas:
 - Other inflammatory cells, as well as multinucleated giant cells, are uncommonly present.
- Vascularity varies from a few scattered vascular structures to prominent dilated vascular spaces with a hemangiopericytomatous pattern.

Monophasic Fibrous Synovial Sarcoma (Fig. 10-45)

- Relatively common tumor in soft tissue sites; uncommon in the head and neck
- Similar histologic features to the spindle cell (fibrous) component of the classic biphasic synovial sarcoma
- Extensive sampling may reveal an epithelioid cell component:
 - Even in the absence of a definitive epithelioid cell component, cells with a more epithelioid cell appearance, including more eosinophilic-appearing cytoplasm and greater cohesive growth

than surrounding spindle cell components, are present.

- More epithelioid-appearing cells show epithelial differentiation by immunohistochemical staining (see below).

Monophasic Epithelioid Synovial Sarcoma

- Rare tumor type of all locations
- Diagnosis and differential diagnosis predicated on cytogenetic and molecular genetic findings (see below)

Poorly Differentiated Synovial Sarcoma

- Uncommon tumor type of all locations
- Associated with three types or patterns:
 - Large cell or epithelioid pattern:
 - Composed of variably sized round nuclei with prominent nucleoli
 - Small cell pattern:
 - Nuclear features similar to other small round cell tumors
 - May form rosette-like structures
 - Spindle cell pattern:
 - Composed of spindle-shaped cells with high-grade nuclear features, marked increase in mitotic activity and necrosis
 - Often richly vascularized with thin-walled, dilated vascular spaces
 - May have cells with a rhabdoid appearance characterized by intracytoplasmic hyaline inclusions

Special Stains

- Histochemistry:
 - Stains for epithelial mucin including PAS (with and without diastase), mucicarmine, alcian blue and colloidal iron show positive material within epithelial cells, pseudoglandular spaces, and intracellular areas:
 - Positive staining remains despite treatment with diastase and hyaluronidase
 - In contrast to adenocarcinoma, the positive material is more conspicuous in pseudoglandular spaces and intracellular clefts than in the epithelial cells
 - Stains for mesenchymal or stromal mucin including colloidal iron and alcian blue show positive material in relation to the spindle cell component and myxoid areas:
 - Material is rich in hyaluronic acid and is removed by prior treatment with hyaluronidase
 - Present in the interstices of the spindle cell areas and myxoid areas
 - Weakly mucicarminophilic and is negative with PAS staining

- Mast cells stain with PAS, alcian blue, and toluidine blue
- Immunohistochemistry:
 - Epithelial cells and spindle cells:
 - Cytokeratins and epithelial membrane antigen (EMA) positive:
 - Intensity of staining is greater in epithelial cells
 - Staining may be present with cytokeratin but not EMA or EMA but not cytokeratin, so both markers should be performed.
 - Immunoreactivity seen for cytokeratins 7, 19, 8/18 (CAM5.2), and 14 in epithelial cells of biphasic tumors:
 - More limited cytokeratin expression in monophasic synovial sarcoma, including CK7 (79%), CK 19 (60%), CK8/18 (45%)
 - Even more limited expression in poorly differentiated synovial sarcoma, including CK7 (50%), CK 19 (61%)
 - Vimentin positive
 - S100 protein is present in up to 30% of cases:
 - Usually present in cases showing expression of epithelial markers
 - May be present in cases lacking expression of epithelial markers
 - CD99 (O13 or Ewing marker) product of *MIC2* gene present in a majority (60% to 70%) of synovial sarcomas:
 - Cytoplasmic and membranous staining
 - bcl-2 positive (75% to 100%) of synovial sarcomas:
 - Diffuse and intense reactivity
 - CD34, endothelial cell markers, melanocytic markers, myogenic markers, and hematolymphoid markers are usually negative.
 - Transducin-like enhancer of split 1 (TLE1) positive (nuclear):
 - Member of groucho/TLE family of genes that encodes transcriptional corepressor implicated in epithelial and neuronal differentiation, body patterning, and hematopoiesis
 - Extremely useful marker for synovial sarcoma serving as a discriminating stain from other sarcomas:
 - Positive in high percentage of molecularly confirmed cases
 - Very rarely expressed in other sarcomas
 - Particularly useful in cytokeratin-negative cases
 - SMARCB1/INI1 protein expression
 - Reduced expression reported in synovial sarcoma with preservation retained in most cases and complete loss of SMARCB1/INI1 protein expression not reported (see epithelioid sarcoma below).
- Electron microscopy:
 - Epithelial cells:
 - Junctional complexes, zonula adherens, or desmosome-like structures seen interconnecting cells:
 - Findings supported by expression of tight junction-related proteins including ZO-1, claudin-1, and occludin
 - Not present in normal synovium
 - Luminal microvilli or villous filopodia can be seen in cells lining or forming gland-like spaces.
 - Spindle cells:
 - Continuous basal lamina separating spindle-shaped cells from epithelioid cells and gland-like structures
- Cytogenetic and molecular genetics:
 - Balanced reciprocal translocation t(X;18) (p11.2;q11.2) found in more than 90% of synovial sarcomas regardless of subtype:
 - Involves fusion of *SS18* (also known as *SYT*) gene on chromosome 18 and either the *SSX1* or *SSX2* gene on the X chromosome (both at Xp11) or rarely with *SSX4* gene (also at Xp11):
 - Two thirds harbor *SS18-SSX1* fusion:
 - Almost all are biphasic synovial sarcomas.
 - One third harbors *SS18-SSX2* fusion:
 - Majority are monophasic synovial sarcomas.
 - Can be detected by reverse transcriptase-polymerase chain reaction (RT-PCR) or fluorescent in situ hybridization (FISH), including a break-apart *SS18* probe
 - Detection can be performed on material from a fine-needle aspiration biopsy, on frozen tissue, or paraffin-embedded tissue.
 - Translocation is sensitive and specific for a diagnosis of synovial sarcoma.

Differential Diagnosis

Biphasic Synovial Sarcoma

- Carcinosarcoma
- Glandular malignant peripheral nerve sheath tumor
- Malignant mesothelioma
- Malignant melanoma
- Papillary thyroid carcinoma:
 - Rare examples of synovial sarcoma may show papillary epithelial cell features that in certain clinical settings of the head and neck may raise concern for a diagnosis of thyroid papillary carcinoma.
 - Presence in papillary thyroid carcinoma of characteristic cytomorphologic (i.e., nuclear) features, true psammoma bodies and immunoreactivity for thyroglobulin and thyroid transcription factor 1

(TTF-1) as well as the absence of a biphasic cell pattern will allow for differentiation.

Monophasic Fibrous Synovial Sarcoma

- Fibrosarcoma
- Leiomyosarcoma
- Hemangiopericytoma
- Spindle cell squamous carcinoma
- Malignant peripheral nerve sheath tumor
- Malignant melanoma

Monophasic Epithelioid Synovial Sarcoma

- Carcinoma (primary or metastatic)
- Epithelioid sarcoma (ES):
 - Rare malignancy of the head and neck:
 - Approximately 4% of all ESs occur in the head and neck.
 - Malignancy of unknown cell of origin showing predominantly epithelioid cytomorphology
 - More common in men than in women; primarily occurs in adolescents and young adults
 - Predilection to flexor surfaces of fingers and hand > wrist and forearm > knee and lower leg (pretibial region) > buttocks, thigh > shoulder, arm, ankle, foot, and toes:
 - Given predilection for the above sites, also referred to as classic, conventional, or distal form of epithelioid sarcoma
 - Histologic features include:
 - Nodular growth with central necrosis and peripheral palisading of tumor cells that at low magnification suggests a granulomatous process (pseudogranulomatous appearance)
 - Admixture of epithelioid and spindle-shaped cells
 - Transitions between the two cell types can be seen
 - Slight nuclear pleomorphism is present
 - Cells have round to oval vesicular nuclei, identifiable central nucleoli, eosinophilic cytoplasm, and ill-defined cell borders
 - Neurotropism and perivascular invasion commonly present
 - Mitotic activity is usually low (typically less than 5 mitoses per 10 high-power fields).
 - Immunoreactive for vimentin, epithelial markers, and CD34:
 - Vimentin (100%)
 - Epithelial membrane antigen (96%), CK8 (94%), and CK19 (72%)
 - More pronounced in epithelioid areas than spindle areas
 - CD34 is positive in >50% of cases.
 - ERG expression (uniform nuclear staining) reported in a significant percentage (38%) of epithelioid sarcomas:
 - Similar staining to that seen in angiosarcomas
 - Negative for ERG gene rearrangement, indicating that ERG expression is not likely related to ERG-involving translocations in epithelioid sarcoma
 - Other endothelial markers (e.g., CD31, others) absent
- Variable immunoreactivity identified for actins (smooth muscle and muscle specific), S100 protein, and neuron-specific enolase
- Loss of nuclear expression of SMARCB1 protein (also known as *INI1*) a tumor-suppressor gene located on long arm of chromosome 22:
 - Expression lost in distal and proximal types of ESs
 - Homozygous deletions or mutations of this gene characteristic of malignant rhabdoid tumor of infancy and their CNS counterpart atypical teratoid/rhabdoid tumor
- Ultrastructural findings include presence of epithelial differentiation (i.e., desmosome-like intercellular junctions, tonofilaments, surface microvilli), and uncommitted fibroblast-like mesenchymal cells
- Cytogenetic and molecular genetics findings reported include:
 - Aberration of the long arm of chromosome 22 (22q11) in proximal and distal types of ESs
 - A variety of chromosomal gains and losses, none specific for epithelioid sarcoma
- Complete surgical resection is the preferred treatment.
- Multiple recurrences often resulting from incomplete resection is characteristic.
- 5-year survival rates range between 50% and 85%.
- 10-year survival rates range between 42% and 55%.
- Recurrence rate of approximately 77% at 10 years
- Metastases occur in approximately 45% of patients:
 - Primarily to the lung followed by regional lymph nodes; less frequently to skin (scalp), bone, brain, liver, CNS, and soft tissue
- Approximately one third of patients die of disease.
- Adverse prognostic features include:
 - Male gender
 - Advanced age at presentation
 - Large tumor size (measuring ≥ 5 cm)
 - Nondistal extremity location
 - High mitotic rate
 - Presence of angioinvasion

- Presence of hemorrhage and necrosis
- Inadequate initial excision
- Multiple recurrences
- Metastatic disease at presentation
- Proximal type of epithelioid sarcoma (ES):
 - Propensity to arise in axial locations including pelvis, perineum, and genital tract
 - Tendency to occur in older adults
 - Histologic findings include:
 - Multinodularity
 - Presence of large epithelioid (carcinoma-like) cells with vesicular nuclei, marked cytologic atypia, and prominent nucleoli
 - Rhabdoid cellular features are commonly present and in any given case may predominate, making differentiation from an extra-renal rhabdoid tumor difficult.
 - Tumor necrosis is commonly seen but does not result in pseudogranulomatous appearance classic or distal epithelioid sarcoma.
 - Rarely, hybrid tumors composed of histologic features of distal ES and proximal ES occur.
 - Immunohistochemical and ultrastructural features similar to those of the distal ES
 - More aggressive biologic course:
 - Tends to be resistant to all forms of therapy
 - Higher (and earlier) rates of tumor-related deaths as compared with distal ES
- SYT-SSX fusion protein that results from the X,18 translocation is an appealing target, as are the proteins overexpressed in synovial sarcoma including bcl-2 and EGFR.
- In the setting of advanced disease improved survival reported in patients:
 - Age less than 35 years of age
 - Response to first-line chemotherapy:
 - The response rate to doxorubicin plus ifosfamide reported to be superior to either agent when given singly
 - Metastasectomy is not associated with improved prognosis.
- Overall prognosis for head and neck synovial sarcoma is not good with tendency to local recurrence as well as for metastatic disease (lung, lymph nodes, and bone):
 - Approximately 20% to 44% develop recurrent tumor.
 - Approximately 24% to 48% develop distant metastases.
 - Overall 5-year survival is 47% to 58%.
 - Mean survival following distant metastasis is less than 2 years.
- Recurrent and/or metastatic synovial sarcoma may demonstrate histologic variation from the primary neoplasm:
 - Biphasic synovial sarcoma may recur or metastasize as a predominantly or exclusively monophasic (epithelioid or spindle cell) synovial sarcoma.
- Favorable prognostic factors include:
 - Childhood patients (15 years or younger)
 - Smaller tumors (less than 5 cm)
 - Distal extremity location
 - Low tumor stage
 - Extensively calcified synovial sarcomas reported to have better long-term prognosis
 - Complete (local) surgical eradication
 - Patients with SYT/SSX2 fusion transcript reported to have longer disease-free survival than patients with SYT/SSX1 fusion transcript:
 - Not universally accepted as an independent prognostic indicator
- Adverse prognostic factors include:
 - Increasing age (>40 years)
 - Larger tumors (≥5 cm)
 - Tumors with poorly differentiated areas
 - Other histologic features reported to have adverse prognostic impact include:
 - Increased mitotic activity (>10 mitoses per 10 high-power fields)
 - Presence of extensive tumor necrosis
 - Histologically higher grade tumors
 - Presence of rhabdoid cells
 - Local recurrence
 - Distant metastasis

Poorly Differentiated Synovial Sarcoma

- Ewing family of tumors
- Rhabdomyosarcoma
- Hemangiopericytoma
- Malignant lymphoma
- Mesenchymal chondrosarcoma
- Carcinoma (primary or metastatic)
- Epithelioid sarcoma
- Neuroblastoma
- Extrarenal rhabdoid tumor

Treatment and Prognosis

- Complete surgical resection is the preferred treatment.
- Nodal metastasis is rare and a neck dissection is not indicated.
- Adjuvant therapy (preoperative and postoperative radiotherapy and chemotherapy) may be beneficial:
 - Improved disease-free and overall survival
 - Chemosensitive regimens that include ifosfamide and doxorubicin or epirubicin result in partial or complete response in approximately 50% of patients.
- Novel therapies such as targeted therapy show promise in the treatment of synovial sarcoma:

Chordoma of the Craniocervical (Base of Skull) Region

(Figs. 10-46 and 10-47)

Definition: Low- to intermediate-grade malignant tumor that arises from and recapitulates the embryonic remnants of the notochord.

- Notochord and chordoma development:
 - Notochord functions as a primitive axial skeleton in humans.
 - From the time of its development in the third to fourth week of gestation, the notochord extends from the sphenoid bone at the junction of the occipital bone, exits its bony confines to run in close apposition to the primitive pharynx,

Fig. 10-46. Nasopharyngeal chordoma.

A, Endoscopic appearance is that of a tan-pink to fleshy mucoid or gelatinous mass. **B** and **C**, MRI sagittal and coronal views showing a large nasopharyngeal soft tissue density eroding into and destroying the bone at the base of the skull. **D**, Characteristic histologic appearance consisting of a lobular neoplastic growth associated with a copious extracellular mucinous matrix.

Continued

**Fig. 10-46, cont'd**

E, Cords, pseudoacini, and trabecular growth. **F**, Epithelioid cells with vesicular to hyperchromatic nuclei and abundant granular to vacuolated-appearing cytoplasm; vacuolization represents glycogen or mucous accumulation that, when extensive, can create cells with a “soap-bubble” appearance referred to as physaliferous cells. Lesional cells are immunoreactive for **(G)** cytokeratin (AE1/AE3), **(H)** S100 protein, **(I)** brachyury (nuclear), and **(J)** E-cadherin (membranous).

Fig. 10-47. Chondroid chordoma.

A and **B**, In addition to histologic foci of conventional chordoma (see [Fig. 10-46](#)), a cartilaginous component is present, including a hypercellular cartilaginous-appearing infiltrate including binucleate cells. Lesional cells are immunoreactive for **(C)** S100 protein, **(D)** EMA, **(E)** brachyury (nuclear), and **(F)** E-cadherin (membranous).

reenters the bone in the basiocciput, and then courses via the apical odontoid ligament through the center of the vertebral bodies to end at the coccyx.

- In the vertebral column, the notochord is divided into segments and disappears by the seventh week of gestation.
- Persistence of notochordal tissue is seen within the nucleus pulposus of the intervertebral disks.
- Chordomas do not arise from the intervertebral body remnants but rather from incomplete regression of notochordal tissue along the notochordal tract during development with common sites of occurrence, including:
 - Sacrococcygeal region, bones of the skull and the vertebra (cervical > lumbar > thoracic)
 - Craniocervical chordomas are identified most frequently in the dorsum sellae, clivus, and nasopharyngeal regions.
- Represent approximately 1% to 4% of all malignant bone tumors
- Most common in the sacrococcygeal region (approximately 50%) followed by the craniocervical/base of skull including the clivus (approximately 35%) and vertebral column (approximately 15%)
- Conventional, chondroid, and dedifferentiated variants recognized
- Myoepithelioma of soft tissue is synonymous with parachordoma; histologically distinct from chordoma; for a more complete discussion see Section 4, Neck, and Section 6, Salivary Glands.

Conventional Chordoma

(see Fig. 10-46)

Clinical

- More common in men than women; can occur in any age but is generally not common before the fourth decade of life
- Most frequent site of involvement in the head and neck is the base of skull, including dorsum sellae, clivus, and nasopharyngeal regions:
 - *Clivus* in Latin means slope.
 - The clivus is a sloping surface (slopes obliquely) formed successively by the basilar part of the occipital bone, the posterior part of the body and then the dorsum sellae of the sphenoid bone that lies anterior to the foramen magnum
 - On axial planes, the clivus sits just posterior to the sphenoid sinuses.
 - Just lateral to the clivus bilaterally is the foramen lacerum, which contains the internal carotid artery proximal to its anastomosis with the circle of Willis
 - Posterior to the clivus is the basilar artery.
 - The pons sits on the clivus.

- Symptoms vary according to the site of occurrence and extension of tumor and include:
 - Diplopia, visual field defects, headaches, pain, nasal obstruction, epistaxis, nasal discharge, soft tissue mass, and endocrinopathies (secondary to destruction of the sella turcica, resulting in loss of pituitary function)
- Radiology:
 - Expansile and destructive osteolytic lesions often associated with a soft tissue mass
 - Nodular and/or cystic deposits of calcification are often seen:
 - Calcifications seen in association with chordomas occur as a result of bone sequestration following its destruction or as dystrophic calcification
 - Destruction of the sella turcica may be seen.
 - Nasopharyngeal chordomas appear as a soft tissue density.

Pathology

Gross

- In comparison with chordomas of other sites (e.g., sacrococcygeal), which can be removed in toto and are well demarcated or encapsulated, those of the base of skull, given the anatomic constraints, often are removed in fragments and are soft, mucoid, or gelatinous with a pink to gray color and a variegated appearance with solid and cystic areas.

Histology

- Pseudoencapsulated tumor separated into a lobular growth by fibrous connective tissue associated with a copious extracellular mucinous matrix
- Neoplastic cells are arranged in cords, sheets, pseudoglands, or clusters.
- Neoplastic cells include:
 - Many appearing epithelioid with vesicular nuclei and abundant, granular to vacuolated-appearing cytoplasm:
 - Vacuolization represents glycogen or mucus and when extensive can appear with a signet ring or a soap bubble appearance compressing the nucleus peripherally and creating the characteristic physaliferous cells.
 - Other cells are small with round to oval hyperchromatic to vesicular nuclei and eosinophilic cytoplasm.
- Nuclear pleomorphism and mitoses are infrequently identified; necrosis and dystrophic calcification can be identified.
- Glandular differentiation, including tubules and acini not present, but pseudoglandular and pseudoacinar foci may be present
- Histochemistry:
 - Diastase-sensitive, periodic acid Schiff–positive, and mucin-positive intracytoplasmic material

TABLE 10-10 Immunohistochemistry of Chordomas: Differential Diagnosis

	CK	EMA	S100	Brachy	E-cad	D2-40	RCC/Pax8	GFAP	CK20/CDX2	MGB

Mets MDC	+	+	–	–	+	–	–	–	–	+
Mets LCB	+	+	–	–	–	–	–	–	–	+

CC, Chondroid chordoma; *Chord*, conventional chordoma; CK, cytokeratins; CS, chondrosarcoma; D2-40, podoplanin; DC, SC, dedifferentiated chordoma, sarcomatous component; E-cad, E-cadherin; EMA, epithelial membrane antigen; GFAP, glial fibrillary acidic protein; ME, myxopapillary ependymoma; *Mets RCC*, metastatic renal cell carcinoma; *Mets GIT*, metastatic gastrointestinal tract adenocarcinoma; *Mets MDC*, metastatic mammary duct carcinoma; *Mets LCB*, metastatic lobular carcinoma of the breast; MGB, mammaglobin; RCC, renal cell carcinoma marker; S100, S100 protein.

*Rare ependymomas may have sparse CK or EMA immunoreactivity.

- Immunohistochemistry (Table 10-10):
 - Cytokeratin, epithelial membrane antigen (EMA), S100 protein, and vimentin positive:
 - Cytokeratin and vimentin consistently positive
 - EMA positive in 90% or more
 - S100 protein positive in 50% to 75%
 - Brachyury positive (nuclear):
 - Transcription factor involved in notochord development
 - Expressed in virtually all cases of chordoma
 - Sensitive and specific marker for chordoma
 - Expression may be lost following decalcification in formic and nitric acid.
 - E-cadherin (membranous):
 - Cadherins are calcium-dependent transmembranous intercellular adhesion molecules that are divided into three classes—E-, P-, and N-cadherin—with distinctive immunologic specificities and tissue distributions.
 - E-cadherin and N-cadherin detected in most chordoma cells irrespective of histologic subtype
 - Reported inverse relationship in tumor aggressiveness based on E-cadherin and N-cadherin:
 - Decreased expression of E-cadherin and increased expression of N-cadherin may underlie the transition from a less to a more aggressive tumor phenotype.
 - Carcinoembryonic antigen may occasionally be positive.
 - Podoplanin (D2-40) negative:
 - Podoplanin considered a sensitive marker in cartilaginous neoplasms (e.g., chondrosarcoma)
 - Glial fibrillary acidic protein and myoepithelial markers (e.g., p63, calponin) negative
- Cytogenetics and molecular genetics:
 - Complex karyotype with loss of chromosomes 3 (especially 3p), 4, 10, and 13
 - Candidate region for sporadic and inherited chordoma development mapped to 1p36.13
 - By comparative genomic hybridization most frequent changes include:
 - Gains of chromosomes 5q, 7q, 12q, and 20
 - Losses of chromosomes 1p, 3p

Differential Diagnosis

- Chondrosarcoma:
 - Usual type
 - Extraskelatal myxoid type
- Liposarcoma, myxoid
- Mucinous adenocarcinoma
- Pleomorphic adenoma
- Myxopapillary ependymoma
- Soft tissue chordoma:
 - Arise in soft tissue locations unrelated to bone, including:
 - Buttock, wrist, leg, toe, thumb, ankle, shoulder, and chest wall
 - Histologically identical to osseous ones
 - Immunoreactive for brachyury
 - Differ from osseous-related chordomas in their greater tendency to occur in distal locations where small size and surgical resectability result in better disease control
 - Existence of soft tissue chordoma implies that notochordal remnants are not a prerequisite for chordoma development.

Treatment and Prognosis

- Complete surgical excision is the preferred treatment:
 - Due to location in base of skull often impossible to surgically eradicate
 - High-dose radiotherapy is utilized in advanced disease where complete resection is impossible.
 - Chemotherapy has no proven efficacy.
- Rarely cured after surgery alone or combined with conventional radiotherapy and more recent evidence suggests that optimal treatment may include stereotactic (gamma knife) radiation therapy or proton beam therapy alone or, when possible, combined with a gross total resection.
- Despite their slow growth, chordomas are relentless neoplasms associated with extensive local infiltration and destruction of adjacent, often vital, structures:
 - Death often due to uncontrollable local disease
 - Metastases are generally a late complication and involve the lungs, bone, liver, and lymph nodes.
- 5-year survival rate for patients under 40 years is 100% as compared with 22% for patients over 40 years of age:
 - Mean survival rates for sacrococcygeal chordomas are slightly better than for cervicofacial chordomas.

Chondroid Chordoma

(see Fig. 10-47)

- Controversial tumor type considered a histologic variant of conventional chordoma with cartilaginous differentiation in association with conventional chordoma:
- Alternative considerations relative to the origin of this tumor include:
 - It is a low-grade or well-differentiated chondrosarcoma.
 - It is a hybrid tumor with chordomatous and cartilaginous differentiation.
- Represent from 5% to 15% of all chordomas and up to 35% of craniocervical (spheno-occipital) chordomas
- Characterized by:
 - More frequent occurrence in women and younger patients than nonchondroid chordoma
 - Virtual exclusive occurrence at the base of skull; rarely may occur elsewhere (e.g., sacrococcygeal)
 - In addition to histologic foci of conventional chordoma, a cartilaginous component is also present:
 - Cartilage can be either benign or malignant.
 - In any given tumor the percentage of each component may vary, representing the dominant

component, the minor component, or approximately equal components.

- Immunohistochemistry (see Table 10-10):
 - S100 protein:
 - Identified in cartilaginous and conventional chordomatous elements
 - Cytokeratin and EMA immunoreactivity:
 - Identified in cartilaginous and conventional chordomatous elements although expression less prominent in cartilaginous foci
 - Brachyury positive (nuclear):
 - Identified in cartilaginous and conventional chordomatous elements
 - E-cadherin positive (membranous):
 - Identified in cartilaginous and conventional chordomatous elements
 - Podoplanin (D2-40) negative
- Purported better prognosis than typical chordomas:
 - Average survival rate for the chondroid chordoma reported to be 15.8 years as compared with 4.1 years for the nonchondroid chordoma
 - Some studies have found no statistical differences in the survival of patients with chondroid chordoma as compared with conventional chordoma, and current opinion is that the conventional chordoma and chondroid chordoma have similar survival rates.
- Existence of chondroid chordoma distinct from low-grade chondrosarcoma has been questioned.
- Separation as a distinct variant of chordoma has been based on immunohistochemical differences between chordoma (S100 protein, epithelial markers, brachyury positive, and D2-40 negative) and chondrosarcoma (S100 protein and D2-40 positive and epithelial markers and brachyury negative)
- Expected immunohistochemical reactive pattern not consistently identified in all cases
- Diagnostic approach may include:
 - Chondroid chordoma for those tumors, showing admixture of conventional chordoma and chondrosarcoma *with* immunoreactivity for epithelial markers anywhere in the tumor
 - Chondrosarcoma for those tumors showing admixture of conventional chordoma and chondrosarcoma *without* immunoreactivity for epithelial markers anywhere in the tumor.

Dedifferentiated Chordoma

- Defined as the presence of conventional or chondroid chordoma with associated sarcomatous component:

- Sarcomatous component most often includes features of undifferentiated pleomorphic sarcoma, but may rarely be fibrosarcoma, osteosarcoma, chondrosarcoma, and rhabdomyosarcoma.
- Rare malignancy; represent less than 6% of all chordomas
- May occur:
 - As a de novo neoplasm
 - Years following radiotherapy for a conventional chordoma (may be considered as postradiation sarcoma)
 - In the absence of prior treatment (i.e., radiotherapy) years after diagnosis and surgical management only of a conventional chordoma
 - Based on the above, theories proposed for the development of dedifferentiated chordomas include spontaneous transformation, radiation induction, and collision tumors.
- Immunohistochemistry (see [Table 10-10](#)):
 - Conventional and chondroid chordoma elements:
 - S100 protein, cytokeratin, EMA, brachyury, E-cadherin positive
 - Podoplanin (D2-40) negative
 - Dedifferentiated (sarcomatous) component:
 - Absence of S100 protein, cytokeratin, EMA, brachyury, E-cadherin
 - Vimentin positive
- Aggressive tumor type:
 - Lethal over relatively short time periods with death often occurring within 1 year of diagnosis
 - Local recurrence and distant metastases, the latter including to the lungs:
 - Metastatic disease may include only conventional chordoma, only sarcomatous component, or both components.

Follicular Dendritic Cell Sarcoma/Tumor (FDCS) ([Fig. 10-48](#))

Definition: Neoplasm of spindled to ovoid cells showing morphologic and phenotypic features of follicular dendritic cells.

Clinical

- Rare tumor
- No gender predilection; typically a tumor of adults:
 - Marked female predominance for inflammatory pseudotumor-like variant
- Usually presents with painless lymphadenopathy most often in the cervical neck region and, less often, in the axillary region
- Extranodal sites of occurrence include:
 - Mucosal sites of the upper aerodigestive tract:
 - Most frequently involves the tonsil and pharynx
 - Other less common sites of occurrence include the palate, soft tissue, and thyroid gland.

- Intra-abdominal sites
- Skin, intestines, soft tissues, mediastinum, lung, and breast
- Clinical presentation of head and neck sites includes enlarging, painless mass that may be associated with dysphagia or other obstructive phenomenon.
- Occur in association with Castleman disease in about 10% to 20% of patients:
 - Most often it is Castleman disease of the hyaline vascular type, and less frequently, the plasma cell type
 - Castleman disease may precede FDCS or the two lesions occur simultaneously.
 - Presence HMGIC rearrangement, a member of the high mobility group protein family, by combined immunocytologic-cytogenetic approach in anti-CD21 reactive follicular dendritic cells has confirmed that a clonal proliferation of follicular dendritic cells occurs in the hyaline vascular variant of Castleman disease and also provides a possible molecular pathway explaining stromal overgrowths and stromal neoplasms developing from this disorder
 - An increased incidence in patients who have been treated for long-standing schizophrenia has been reported.
- Inflammatory pseudotumor-like variant of FDCS:
 - Purportedly a distinctive variant
 - Differs from conventional FDCS by its:
 - Marked female predominance
 - Selective localization in intra-abdominal sites, especially the liver and spleen
 - Frequent presence of systemic symptoms
 - Indolent behavior despite an intra-abdominal location
 - Dispersed distribution of tumor cells and prominent lymphoplasmacytic infiltration and consistent association with EBV
 - Unclear whether these tumors represent a true FDCS or a variant of inflammatory pseudotumor
 - FDCS in other organs are consistently EBV negative and HHV-8 negative.

Pathology

Gross

- Usually well circumscribed and solid
- In the mucosa of the upper aerodigestive tract are usually polypoid with an intact surface epithelium; medium size of about 5 cm but may range widely in size from a few centimeters to as large as 20 cm as might occur in retroperitoneum

Histology

- In lymph nodes, there is partial or complete effacement of the nodal architecture.

Fig. 10-48. Follicular dendritic cell sarcoma.

A, Postmortem specimen of a large submucosal that originated in the palatine tonsil. **B**, Submucosal cellular proliferation with diffuse to focally fascicular and whorled growth. **C**, Cellular proliferation composed of round to oval to elongated (spindle-shaped) nuclei with vesicular or granular-appearing chromatin and indistinct cell borders; immunoreactivity is present for **(D)** CD21, **(E)** CD23, and **(F)** CD35.

- In mucosal sites of the upper aerodigestive tract there is usually a submucosal cellular proliferation.
- Growth characteristics include diffuse, storiform, fascicular, and whorled.
 - Uncommonly there may be fluid-filled cystic spaces, some in a perivascular location resembling thymoma or amyloid change.
- Cellular proliferation includes oval to spindle-shaped cells with round to oval, uniform-appearing, elongated nuclei with vesicular or granular-appearing chromatin, inconspicuous nucleoli, and pale to slightly eosinophilic cytoplasm with indistinct borders.
- Scattered multinucleated giant cells may be identified; pseudonuclear inclusions may be present.
- Absent to scattered mitotic figures (0 to 10 mitoses per high-power fields) can be found but atypical mitoses, significant pleomorphism, and necrosis are usually absent; however, in some cases marked nuclear pleomorphism with increased mitoses, atypical mitotic figures and necrosis (confluent foci) may be identified.
- A background lymphocytic infiltrate either as individual cells or in clusters can be identified throughout the tumor, and often in a perivascular (cuffing) location; occasional germinal centers can be identified.
- Immunohistochemistry:
 - Positive for one or more follicular dendritic markers including CD21, CD35, CD23
 - In addition, consistent expression is present for follicular dendritic cell-specific markers (e.g., Ki-M4P, CAN.42)
 - Diffuse strong staining for clusterin identified in 100% of cases, including cases that were negative for traditional markers (CD21, CD23, CD35), but classified based on characteristic ultrastructural features (see below):
 - Staining for clusterin is useful in classification of dendritic cell tumors, particularly when the more common markers of follicular dendritic cells are not expressed.
 - Usually reactive for vimentin, fascin, desmoplakin, HLA-DR, and epidermal growth factor receptor (EGFR)
 - Variably reactive for epithelial membrane antigen (EMA)
 - EMA reactivity is present despite the fact that normal follicular dendritic cells are EMA negative.
 - Variable reactivity for S100 protein, CD68
 - Typically negative for cytokeratins, CD45, CD20, although exceptionally these markers may be present
- Consistently negative for CD1a, CD3, CD34, CD79a, CD30, melanocytic markers, desmin, and vascular markers
- EBV negative (except in the inflammatory pseudotumor-like variant) and human herpesvirus-8 negative
- Proliferation indices by Ki67 range from 1% to 25%.
- Electron microscopy:
 - Presence of complex interdigitating (villous) cytoplasmic processes or extensions, often joined through numerous cell junctions, including well-formed desmosomes
- Cytogenetics and molecular genetics:
 - Gene rearrangement studies have revealed germline configuration for the immunoglobulin heavy chain and T-cell receptor β , δ , and γ genes.

Differential Diagnosis

- Wide variety of tumor types, including (but not necessarily limited to) carcinoma, melanoma, sarcoma, lymphoma, and other dendritic cell tumors (e.g., Langerhans cell granulomatosis, interdigitating dendritic cell tumor):
 - Interdigitating dendritic cell tumor/sarcoma (IDCT) consistently expresses S100 protein and vimentin, shows variably weak reactivity for CD 68, lysozyme, and CD45, and is negative for CD21, CD23, CD35, CD1a, Langerin, cytokeratins, EMA, CD30, and CD34.
 - Rare examples showing mixed morphology of FDCS and interdigitating dendritic cell sarcoma
 - In general, an extensive immunohistochemical work-up is indicated to exclude the other tumor types and in establishing the diagnosis of FDCS.

Treatment and Prognosis

- Treatment includes surgical excision with or without adjunctive therapy (i.e., radiotherapy, chemotherapy).
- Overall behavior is rather indolent and has been likened to low-grade sarcomas:
 - From 40% to 50% of patients develop local recurrence after a latency period of several years
 - Distant metastasis may occur but is considered uncommon:
 - Common sites of metastasis include lymph nodes, lung, and liver.
- Death due to local recurrence and/or distant metastasis may occur.
- At least 10% to 20% of patients ultimately die of disease, often after a long period of time.
- Poorer prognosis associated with:
 - Intra-abdominal presentation
 - Significant cytologic atypia (high-grade features)

- Extensive coagulative necrosis
- High proliferative index
- Larger size (greater than 6 cm)
- Lack of adjuvant therapy has a poorer prognosis

- Rare malignancy
- More commonly occurs in the sinonasal tract (see Section 1)
- Histologic and immunohistochemical similar to that seen in sinonasal counterparts

Leiomyosarcoma (LMS)

Definition: Malignant neoplasm with smooth muscle differentiation.

- LMS is covered in greater detail in the section on the sinonasal tract.
- For more complete discussion see Section 1, Sinonasal Tract.

Liposarcoma

Definition: Malignant neoplasm with adipocyte cell differentiation.

- For more complete discussion see Section 6, Larynx.

Malignant Peripheral Nerve Sheath Tumors (MPNST)

Definition: Malignant tumor of peripheral nerves or having differentiation along the lines of various elements of the nerve sheath.

Synonyms: Malignant schwannoma; neurogenic sarcoma; neurofibrosarcoma

- For more complete discussion see Section 4, Neck.

Angiosarcoma

Definition: Malignant neoplasm with endothelial cell differentiation.

- For more complete discussion see Section 1, Sinonasal Tract.

Teratocarcinosarcoma (Malignant Teratoma) of the Pharynx

Definition: Malignant neoplasm composed of cells from all three germ layers.

SECONDARY NEOPLASMS TO THE PHARYNX

- Metastatic tumors to the pharynx occur via hematogenous spread and may occur in the setting of a known primary neoplasm outside the head and neck or may represent the initial manifestation of disease (i.e., occult metastasis):
 - More often, metastasis to the upper aerodigestive tract is part of widely metastatic disease from a known index malignant tumor.
 - Metastatic disease to these sites may occur at presentation of the primary tumor or may occur years following treatment for the primary tumor.
- Virtually every conceivable malignancy may metastasize to the upper aerodigestive tract:
 - For gnathic metastases, the most common primary malignant tumors are (in descending order): breast, kidney, lung, prostate, thyroid, colon, other
 - For soft tissue metastases:
 - Females: breast, other
 - Males: lung > kidney, skin, other

Anatomy of the Neck

ANATOMY OF THE NECK

- Prominent landmarks in the neck are the hyoid bone, thyroid cartilage, trachea, and sternocleidomastoid muscles.
- The neck is divided into the anterior and posterior triangles by the sternocleidomastoid muscles (Fig. 11-1):
 - Anterior triangle:
 - Lateral limit: anterior border of the sternocleidomastoid muscle
 - Medial limit: anatomic midline of the neck
 - Above: lower border of the mandible
 - Subdivisions of the anterior triangle include:
 - Carotid triangle
 - Submandibular (submaxillary) triangle
 - Inferior carotid (muscular) triangle
 - Submental or suprahyoid triangle
 - Contents of the anterior triangle include:
 - Common carotid artery with its internal and external branches
- Cranial nerves IX through XII
- Internal jugular vein
- Superficial and deep cervical lymph nodes
- Posterior triangle:
 - Anteromedial: posterior border of the sternocleidomastoid muscle
 - Posteriolateral: anterior border of the trapezius muscle
 - Below: the clavicle
- Contents of the posterior triangle include:
 - Subclavian artery
 - External jugular vein
 - Branches of the cervical plexus
 - Cranial nerve XI (accessory)
 - Numerous lymph nodes, including the posterior cervical and supraclavicular lymph nodes

Non-Neoplastic Lesions of the Neck

CLASSIFICATION OF NON-NEOPLASTIC LESIONS OF THE NECK (Box 12-1)

BOX 12-1 Classification of Non-neoplastic Lesions of the Neck

Developmental Cystic Anomalies

- Branchial cleft anomalies
- Thyroglossal duct cyst
- Cervical thymic cyst
- Bronchogenic cyst
- Dermoid cyst
- Others

Infectious and Related Diseases/Lesions

- Bacterial and mycobacterial
- Fungal

- Viral
- Protozoal
- Sarcoidosis
- Others

Reactive, Inflammatory, and Tumor-like Lesions

- Mesenchymal lesions
- Others

BENIGN CYSTIC LESIONS OF THE CERVICAL NECK

- Cystic lesions of the neck represent a diverse group of lesions listed in [Box 12-2](#).

BRANCHIAL ANOMALIES (BA)

Definition: Congenital malformations related to the branchial apparatus.

Embryology

- Branchial apparatus appears around the fourth week of gestation and consists of a paired series of six arches, five pouches, and five clefts or grooves.
- Embryologic development of the head and neck structures can be classified through the development of the branchial apparatus, including arches (mesoderm), clefts (ectoderm), and pharyngeal pouches (endoderm) ([Table 12-1](#)).

BOX 12-2 Non-Neoplastic Cystic Lesions of the Neck

Cystic Lesions of the Cervical Neck

Developmental Cysts

- Branchial cleft cyst
- Thyroglossal duct cyst
- Cervical thymic cyst
- Bronchogenic cyst
- Parathyroid cyst
- Others

- Branchial apparatus gives rise to most of the important structures of the head and neck, including the face, oral cavity, ears, and neck.

Clinical

- No gender predilection; occur at any age, but most commonly become evident in young adults
- Predominantly occur in the lateral neck along the anterior portion of the sternocleidomastoid muscle:
 - Also seen in the area around the external ear, in the external auditory canal, and in the parotid gland
- Generally, occur as an isolated phenomenon but may be familial or may rarely be associated with other congenital defects, including:
 - Malformed auricles
 - Hearing abnormalities
 - Patent ductus arteriosus
 - Tear duct atresia

Branchial Cysts, Sinuses, and Fistulas

- Branchial cleft anomalies are divided according to the branchial apparatus involved and are further divided into cysts, sinuses, or fistulas:
 - *Cysts* are epithelial-lined structures that may occur as an isolated lesion or may occur in association with a sinus or fistula.

TABLE 12-1 Branchial Apparatus and Derivatives

	Arches (Mesoderm)	Pharyngeal Pouches (Endoderm)	Clefts (Ectoderm)
First	<i>Cartilage bar (Meckel cartilage):</i> Ramus and body of mandible Maxilla Incus (body) Malleus (head and neck) Part of pinna of ear <i>Muscles and ligaments:</i> Temporalis Masseter Pterygoids (medial and lateral) Digastric (anterior belly) Mylohyoid Tensor tympani Tensor veli palatini Anterior two thirds of tongue Sphenomandibular lig. Anterior malleolar lig. <i>Innervation:</i> Trigeminal (maxillary and mandibular divisions) <i>Vasculature:</i> Facial artery	Epithelial lining of the middle ear cavity, inner part of the tympanic membrane, eustachian tube, mastoid air cells	Epithelial lining of the external auditory canal, and outer part of the tympanic membrane
Second	<i>Cartilage bar (Reichert cartilage):</i> Incus (long process) Malleus (manubrium) Stapes (long process) Styloid process Hyoid (lesser horn and upper body) Part of pinna of ear <i>Muscles and ligaments:</i> Facial (auricularis, buccinator, frontalis, occipitalis, orbicularis oculi, oris platysma) Digastric (posterior belly) Stapedius Stylohyoid Stylohyoid lig. <i>Innervation:</i> Facial <i>Vasculature:</i> Lingual branch of ext. carotid artery	Epithelial lining of the tonsillar fossa and palatine tonsil	None
Third	<i>Cartilage bar:</i> Hyoid (lower body and greater horn) <i>Muscles and ligaments:</i> Stylopharyngeus Palatopharyngeus Posterior third (base or root) of tongue <i>Innervation:</i> Glossopharyngeal <i>Vasculature:</i> Internal carotid artery	Inferior parathyroid glands, thymus, pyriform sinus	None
Fourth	<i>Cartilage bar:</i> Thyroid <i>Muscles and ligaments:</i> Cricothyroid Levator palatini Posterior third (base) of tongue <i>Innervation:</i> Vagus (superior laryngeal branch) <i>Vasculature:</i> Arch of aorta Right subclavian artery	Superior parathyroid glands C-cells of ultimobranchial body	None
Fifth and sixth	<i>Cartilage bar:</i> Cricoid Arytenoids <i>Muscles and ligaments:</i> Intrinsic muscles of larynx Upper esophageal muscles <i>Innervation:</i> Vagus (recurrent laryngeal) <i>Vasculature:</i> Pulmonary arteries Ductus arteriosus	C-cells of ultimobranchial body (5th pharyngeal pouch) 6th pharyngeal pouch: none	None

- *Sinuses* are tracts with a single opening; the opening may be to skin, representing a branchial cleft or ectodermally derived sinus tract (cutaneous sinus tract), or to mucosa, representing a branchial pouch or endodermally derived sinus tract (mucosal sinus tract).
- *Fistulas* are tracts with two openings, which can be cutaneous or mucosal.

Clinical

- Cysts present as nontender, fluctuant masses in appropriate locations; cysts may become inflamed and abscesses may develop, potentially associated with dysphagia, dyspnea, or stridor.
- Sinuses and fistulas are associated with discharge of mucoid and/or purulent secretions from the tract opening.
- Up to 10% of cases may be bilateral.
- Histogenesis of branchial cleft anomalies is controversial:
 - Among the structures proposed as the origins for these anomalies include the branchial apparatus (considered to represent the origin for these abnormalities), salivary gland inclusions, and thymic duct.

First Branchial Anomalies (Fig. 12-1)

Clinical

- In comparison to second branchial anomalies, first branchial anomalies are uncommon, representing from 1% to 8% of all branchial apparatus defects.
- Typically occur in the area of the external ear and may include cysts, sinuses, and fistulas.
- First branchial anomalies may be identified in a variety of locations, including pre-, post-, or infra-auricular, at the angle of the jaw, associated with the earlobe, and in the external auditory canal or involving the parotid gland.
- Involvement of the external auditory canal may result in otalgia or otorrhea.
- Parotid involvement may result in an intra- or periparotid mass that may be mistaken for a parotid gland tumor.

Pathology

Gross

- Majority of first BA are cysts, representing more than two thirds (68%) of these anomalies:
 - Appear as solitary cystic lesions without an associated sinus tract
- Sinuses and fistulas equally make up the remainder of these lesions:
 - Fistula tract in first branchial anomalies may extend from the skin over or through the parotid and open in the external auditory canal.

Fig. 12-1. First branchial cleft cyst.

A, Infra-auricular, freely movable, and fluctuant mass.

B, Left, First branchial cleft cyst (Work type I) is composed of keratinizing squamous epithelial lining devoid of adnexal structures; a dense lymphoid infiltrate is seen in the cyst wall; **Right,** first branchial cleft cyst (Work type II) is composed of keratinizing squamous epithelial lining with associated adnexal structures.

Microscopic

- First branchial lesions can be divided into two types as defined by Work, which are referred to as type I and type II lesions:
 - Type I:
 - Contains only ectodermal elements, including keratinizing squamous epithelium without adnexal structures (i.e., hair follicles, sebaceous glands, sweat glands) or cartilage, thereby duplicating the membranous external auditory canal
 - Represents a first cleft anomaly only
 - Typically are located medial, inferior, or posterior to the concha and pinna
 - Sinuses parallel the external auditory canal and end in a blind sac at the level of the mesotympanum.
 - External auditory canal is intact and hearing is normal.
 - Type II:
 - Have ectodermal and mesodermal elements, including keratinized squamous epithelium, cutaneous adnexa, and cartilage, thereby duplicating the external auditory canal and pinna
 - Typically localize to a point just below the angle of the mandible
 - Sinus or fistula tracts extend upward over the angle of the mandible through the parotid gland toward the external auditory canal.
- Type II anomalies are more intimately associated with the parotid gland than type I anomalies, although parotid tissue may be found in association with type I sinus or fistula tracts.
- Tracts associated with type II defects may terminate short of the external auditory canal or may open up in the external auditory canal near the junction of the cartilaginous portion and osseous portion of the canal; communication with the middle ear is uncommon.
- For either type I or type II defects, an associated prominent lymphoid component is not usually present, contrasting with second BA; only when inflamed or infected will there be an associated lymphoid component.
- Some authorities recommend that, due to the overlapping histology between Work types I and II, all first branchial cleft anomalies be classified only as cysts, sinuses, or fistulas.
- Unless inflamed, a prominent lymphoid component is not seen, contrasting to the findings that can be seen in second branchial cysts.

Differential Diagnosis

- Epidermoid cyst
- Dermoid cyst

Treatment and Prognosis

- Regardless of the histology, complete surgical excision is the preferred treatment:
 - Inadequate excision results in recurrence and increased risk of infection.
 - Incision and drainage are indicated in cases in which abscesses have developed, and in this situation complete surgical excision must wait until resolution of the infection.
 - Type II anomalies are often intimately associated with the parotid gland, necessitating a superficial parotidectomy to ensure complete excision.
 - Although there is no consistent relationship between the tract and the facial nerve as it courses through the parotid gland, exposure and dissection of the nerve and its branches are required in Work type II anomalies.

Second Branchial Anomalies

(Figs. 12-2 through 12-4)

Synonym: Second branchial cysts also referred to as (cervical) lymphoepithelial cyst

Clinical

- Accounts for the majority of the branchial apparatus anomalies, representing from 92% to 99% of all cases
- Equal gender predilection; typically occurs in the third through fifth decades of life:
 - Uncommon in patients older than 50 years of age:
 - Less than 3% of cysts present after the age of 50
 - Lateral neck cysts in patients 50 years of age and older should prompt diagnostic consideration for a metastatic cystic squamous cell carcinoma (see Chapter 13).
- Occur along the anterior border of the sternocleidomastoid muscle; most common at the level of the angle of the mandible
- Present as a painless, fluctuant neck mass that may increase in size in the face of an upper respiratory tract infection, at which time they may become painful
- Cysts are much more common than fistulas.
- Sinuses and fistulas are most often identified at birth or in early childhood, presenting as a small opening above the clavicle through which mucoid secretions may be expressed; these are divided into three types:
 - Incomplete external, with an external (cutaneous) but no internal (pharyngeal) opening
 - Incomplete internal, with a pharyngeal but no cutaneous opening

Fig. 12-2. Second branchial cleft cyst.

A, Second branchial cleft cyst occurring along the anterior border of the sternocleidomastoid muscle as painless, fluctuant neck mass. **B**, Axial CT, enhanced: fluid-filled cyst (c) anterior to the left sternocleidomastoid muscle (s). The thin-walled cyst does not enhance after administration of intravenous contrast. Jugular veins (arrowheads). **C**, Axial contrast-enhanced CT shows a cyst in the right neck with a fairly thick, enhancing rim. The cyst is behind the submandibular gland, lateral to the carotid sheath structures, and along the anterior margin of the sternocleidomastoid muscle. This was an infected second branchial cleft cyst. (**B**, **C**, from Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 2244, Fig. 37-14, D.)

- Complete, with pharyngeal and cutaneous openings:
 - The cutaneous opening is seen anywhere along the anterior border of the sternocleidomastoid muscle from the hyoid bone to the sternum, with the epithelial tract coursing cephalad,

between the internal and external carotid arteries, over cranial nerves IX and XII, deep to the posterior belly of the digastric muscle and terminating close to the middle constrictor muscle or with an internal opening in the pharyngeal wall and/or tonsillar region.

Fig. 12-3. Second branchial cleft cyst.

A, Resected, smooth-walled second branchial cleft cyst. Histologically, branchial cleft cyst wall lining epithelium is typically lined by **(B)** stratified squamous epithelium and **(C)** less frequently a purely ciliated columnar epithelium. Although not depicted here, the cyst wall typically contains a nodular or diffuse lymphoid infiltrate often with germinal centers.

- Radiology:
 - Cysts appear as well-defined, low-density lesions surrounded by a thin, uniform wall.
 - Noninflamed cysts have no or minimal CT mural enhancement.
 - Infected cysts have increased CT density of the central fluid with rim enhancement and poorly defined cyst wall.
 - Fistulas or sinus tracts may extend either toward the skin surface, suprathyroid fossa, as well as between the internal and external carotid arteries.
- Histogenesis of second branchial cleft cysts is controversial:
 - Among the structures proposed as the origins for these anomalies include the branchial apparatus (considered to represent the origin for these abnormalities), salivary gland inclusions, and thymic duct.

Pathology

Gross

- Cysts are thin-walled cystic structures filled with cheesy material or serous, mucoid, or purulent fluid; nodular excrescences may be seen lining the cyst wall.

Histology

- Cyst lining epithelium is predominantly a stratified squamous epithelium seen in approximately 90% of cases; less frequently a purely columnar epithelial lining or a mixed lining may be seen.
- Cyst wall typically contains a nodular or diffuse lymphoid infiltrate often with germinal centers.
- Fibrosis and granulation tissue may be prominent and even replace the surface epithelium in cases associated with repeated infections.

Fig. 12-4. Branchial cleft fistula.

A, Cutaneous drainage in lower neck above the clavicle. **B**, Radiologic imaging showing a "complete" sinus tract extending uninterruptedly from the pharynx to its cutaneous opening. **C**, Surgically excised fistula tract, including its cutaneous end (*lower right*).

- Fistulas often are composed of a stratified squamous epithelium associated with the external segments and a columnar epithelium with the internal segments.
- There is no evidence of thymic (thymic cyst) or thyroid tissue (thyroglossal duct cyst).

Immunohistochemistry

- Cytokeratin(s) positive
- p16 negative:
 - Branchial cleft cysts can exhibit focal patchy weak to strong reactivity limited to the superficial squamous epithelium.
 - Absence of p16 may be helpful in distinguishing branchial cleft cyst from metastatic oropharyngeal nonkeratinizing squamous cell carcinoma but it is not as useful in cases of metastatic keratinizing squamous cell carcinoma as the latter are typically p16 negative.
- Thyroglobulin, TTF1, PAX8 negative
- Low proliferation rate (less than 5%) by Ki67 (MIB1) staining

Differential Diagnosis

- Thymic cyst
- Thyroglossal duct cyst
- Metastatic cystic squamous cell carcinoma, including HPV-associated and non-HPV-associated:
 - Absence of cytologic features of malignancy excludes the diagnosis of a metastatic cystic squamous cell carcinoma
 - Some examples of cystic metastatic squamous cell carcinoma may be composed of relatively bland cytomorphic features but even in such cases there are foci of cytologically atypical/malignant epithelial cells characterized by pleomorphic nuclei and increased mitotic activity:
 - Increased proliferation rate as determined by Ki67 (MIB1) staining would be present in metastatic carcinoma and absent in branchial cyst.
 - Diffuse and strong (nuclear and cytoplasmic) p16 immunoreactivity, representing a surrogate

marker for HPV-16, would confirm the diagnosis of metastatic cystic HPV-associated carcinoma of oropharyngeal origin, differentiating it from a branchial cleft cyst, which should be nonreactive for p16.

- p16 may be overexpressed in almost 50% of benign branchial cleft cysts potentially limiting the diagnostic utility of p16 in this setting; in such an occurrence molecular testing (in situ hybridization, PCR) would be necessary to confirm presence of HPV and the malignant nature of the cyst.
- Confusion and controversy exist between the diagnosis of metastatic cystic squamous cell carcinoma and that of a carcinoma arising in a branchial cleft cyst (so-called branchial cleft carcinoma or branchiogenic carcinoma); criteria for the diagnosis of a branchiogenic carcinoma include:
 - The tumor occurs along the line extending from a point anterior to the tragus along the anterior border of the sternocleidomastoid muscle to the clavicle.
 - Histology supports origin from a branchial cleft-derived structure (i.e., situated in the lateral aspect of the neck).
 - Histology supports carcinoma arising in the wall of an epithelial-lined cyst.
 - A minimum of 5-year follow-up demonstrates no evidence of a primary source for this neoplasm.
 - Despite the fulfillment of these criteria, it is highly unlikely that carcinoma arises in a branchial cleft cyst; rather, these cystic squamous cell carcinomas take origin from a primary tumor in Waldeyer tonsillar ring:
 - Primary (Waldeyer ring) neoplasm may be so small as to defy clinical detection but nevertheless is capable of metastasizing.
 - Histology demonstrates partial or complete replacement of the lymph node by an epithelial-lined structure with central cystic change; the epithelium varies from areas that are bland, composed of uniform cells lacking pleomorphism, crowding, or loss of polarity, to overtly malignant-appearing epithelium composed of pleomorphic cells with increased cellularity, mitoses, and a loss of polarity.
- Metastatic papillary thyroid carcinoma:
 - Absence of architectural and cytomorphologic features associated with papillary thyroid carcinoma would differentiate metastatic papillary thyroid carcinoma from second BA.
 - Cystic metastatic papillary thyroid carcinoma to the neck may occur in the absence of a known history of a primary thyroid carcinoma and/or as an occult metastasis. Further, the primary thyroid-based carcinoma may be very small and clinically

difficult to detect. Most often the metastasis originates from the ipsilateral thyroid lobe. Given the clinical scenario of unsuspected/unknown primary thyroid carcinoma, the histology of the neck mass may include a flattened/attenuated epithelial lining without papillary architecture histologically simulating the appearance of a branchial cleft cyst:

- Attention to the nuclear features may alert the pathologist to the possible presence of metastatic papillary thyroid carcinoma.
- In suspect cases, thyroglobulin, thyroid transcription factor 1 (TTF-1), and PAX8 reactivity would be present in metastatic papillary thyroid carcinoma and absent in BAs:
 - Thyroglobulin reactivity is the single best marker for lesions of thyroid follicular epithelial cell origin and is generally absent in all other (nonfollicular epithelial cell origin) lesions.
 - TTF-1 reactivity is not unique for follicular epithelial-derived lesions of the thyroid but can be present in other lesion types, including (but not limited to) medullary thyroid carcinoma and pulmonary adenocarcinoma; in contrast, thyroglobulin reactivity is a dedicated marker for lesions of thyroid follicular epithelial cell origin and represents the preferred immunomarkers in the evaluation for metastatic carcinomas of thyroid follicular epithelial cell origin.
 - Regardless of the histologic (nuclear) features, thyroid tissue located in lymph nodes situated lateral to the great neck vessels represents metastatic thyroid carcinoma; see Section 8, Thyroid Gland, for more complete discussion.

Treatment and Prognosis

- Complete surgical excision is the preferred treatment.
 - Depending on the extent of the fistula tract, a tonsillectomy may be needed.

Third Branchial Anomalies

- Third BAs are rare.
- May present as recurrent neck abscesses associated with stridor or as recurrent episodes of acute suppurative unilateral thyroiditis
- A sinus or fistula open externally anterior to the lower third of the sternocleidomastoid muscle:
 - If complete, the internal opening of the sinus or fistula is in the piriform sinus following passage of the tract along the carotid sheath penetrating the thyrohyoid membrane cranial to the superior laryngeal nerve.

- Cysts occur anywhere along the sinus tract but are most commonly found in the region of the laryngeal ventricle or in the anteroinferior cervical triangle.

Pathology

Histology

- Cysts are lined by a stratified squamous epithelium or ciliated epithelium; an associated marked lymphocytic cell infiltrate may be present.
- Thymic tissue, derived from the third branchial cleft pouch, may or may not be present.

Treatment and Prognosis

- Complete surgical resection of a third BA (cyst, sinus, fistula) is the preferred treatment and is necessary to prevent recurrence:
 - Surgical procedure may require a subtotal thyroidectomy.

Fourth Branchial Anomalies

- Fourth BAs are extremely rare.
- The majority of patients presents before the age of 20 years.
- Clinical manifestations of fourth BAs are similar to those of third BAs, including recurrent neck abscesses or recurrent episodes of acute suppurative unilateral thyroiditis.
- Almost all fourth BAs are sinuses that may originate from the piriform sinus:
 - The sinus tract usually has an internal opening at the apex of the piriform sinus caudal to the superior laryngeal nerve, descends translaryngeally beneath the thyroid cartilage, exiting the larynx near the cricothyroid joint below the inferior constrictor muscle, and then continues superficial to the recurrent laryngeal nerve ending in the paratracheal region or in the thyroid gland.
- Like third BAs, fourth BAs may or may not include thymic tissue.
- Complete surgical resection of a fourth BA is the preferred treatment and is necessary to prevent recurrence:
 - Surgical procedure may require a subtotal thyroidectomy.

THYROGLOSSAL DUCT CYST

Definition: Persistence and cystic dilatation of the thyroglossal duct in the midline of the neck.

Embryology

- The thyroid gland is the first endocrine gland to appear during embryonic development.
- Thyroid gland derives from three primordium, the median anlage, and lateral anlages:
 - Median anlage develops around the 24th day of gestation as a small, median endodermal thickening on the primitive pharynx; this thickening forms a diverticulum, which is attached to the tongue by a narrow tube, the thyroglossal duct; its opening in the base of the tongue constitutes the foramen cecum.
 - Proximal opening persists as the foramen cecum of the tongue
- As a result of further cellular proliferations, the hollow thyroid diverticulum obliterates and divides into the right and left lobes, connected by the isthmus around the seventh week of gestation.
- During development the thyroid descends and assumes a definitive position in the anterior neck; by this time the thyroglossal duct degenerates.

Clinical/Pathology

- See Section 8, Thyroid Gland, for a more complete discussion including illustrations.
- Majority of cases occurs in the midline of the neck above the thyroid isthmus but below the level of the hyoid bone:
 - Thyroglossal duct cysts are nearly always connected to the hyoid bone.
 - Uncommonly, thyroglossal duct cysts may occur lateral to midline but do not occur in the lateral portion of the neck (i.e., lateral to the jugular vein).
- Clinical presentation of an uninfected thyroglossal duct cyst is usually that of an asymptomatic midline neck mass:
 - Mass typically moves upward on swallowing.
 - Inflamed or infected thyroglossal duct cysts may be associated with tenderness and pain.
 - Extrinsic airway compression in neonates with apnea, cyanosis, and respiratory compromise may uncommonly occur.
- Thyroglossal duct cysts are smooth-walled, cystic structures that usually measure less than 2 cm.
- In noninflamed cysts, the cyst lining is respiratory (columnar) epithelium but may also include squamous epithelium.
- Presence of thyroid tissue in the cyst wall varies and may be dependent on the extent of specimen sampling; in generally, thyroid tissue can be found in more than 60% of the cases.
- Thyroid tissue may be normal, hyperplastic, and nodular or neoplastic (see below).
- Surgery is the preferred treatment; en bloc surgical resection of the cyst, the middle third of the hyoid bone (Sistrunk procedure), and the suprahyoid tract up to the foramen cecum; this extended surgery prevents recurrence:
 - Adequate surgery results in cure with low, if any, recurrences.

- Benign and malignant neoplasms may occur in the setting of a thyroglossal duct cyst.
- C-cell-related lesions, including medullary carcinoma, do not occur in thyroglossal duct cysts due to the different embryologic derivation of the C-cells.

CERVICAL THYMIC CYST (Fig. 12-5)

Definition: Cervical thymic tissue sequestered from the main thymic gland during its embryologic descent:

- Sequestered thymic tissue may be solid (so-called accessory cervical thymic tissue) or cystic (cervical thymic cyst).

Embryology and Anatomy

- Thymus develops in the sixth week of gestation, arising primarily from the third branchial pouch (mesoderm); the fourth branchial pouch may provide minimal contribution to the development of the thymus.

- Thymic primordia descend in the neck along the course of the carotid sheath.
- Connection of the paired primordia to the pharynx is retained by the thymopharyngeal ducts.
- During the eighth week of gestation the thymic primordia fuse in the midline of the neck and then descend into the mediastinum.
- Failure of descent or failure to involute results in thymic abnormalities, including cervical thymic cyst.
- Cervical thymic cysts are considered to be congenital, although mediastinal thymic cysts are thought to be acquired.

Clinical

- Cervical thymic cysts are uncommon.
- Occur slightly more often in men; the majority of cervical thymic cysts (67%) occurs during the first decade of life with the rest occurring in the second to third decades:
 - Rarely, cervical thymic cysts occur in adults.

Fig. 12-5. Cervical thymic cyst.

A, Multilocular smooth walled cystic proliferation with focal solid areas. **B** and **C**, Epithelial lined cyst with identification of lymphoid follicles and Hassall corpuscles within the cyst wall. **D**, A rather common finding in thymic cysts is the presence of cholesterol granulomas.

- Found anywhere between the angle of the mandible and the sternum, including the lateral and midline neck
- Majority of patients presents with a slow-growing, painless neck mass that may transiently increase in size during a Valsalva movement; uncommonly, the clinical presentation may include dyspnea, dysphagia, hoarseness, or pain.
- Rarely (if ever) associated with a sinus or fistula
- May represent an isolated cystic lesion in the neck, may extend into the mediastinum, or may be in continuity with an intrathoracic thymus gland:
- Radiology:
 - Connections to intrathoracic structures result in abnormal radiologic findings.
 - Appearance of cervical thymic cyst on CT can be characteristic:
 - The course of the descent of embryologic thymic tissue in the neck to the mediastinum indicates the potential site of deposition of an ectopic cervical thymic cyst.
 - In a child, a cystic lesion that has an intimate relationship to the carotid sheath is likely to be a thymic cyst.

Pathology

Gross

- Cysts are unilocular or multilocular, usually contain clear, serous-appearing fluid, and may measure up to 15 cm in greatest dimension.
- Cyst wall lining is smooth or trabeculated; the cyst wall varies in thickness.

Microscopic

- Cyst wall is lined by cuboidal, columnar, or squamous epithelium, and by definition the wall contains thymic tissue, including characteristic epithelial islands referred to as Hassall corpuscles, as well as lymphoid follicles; the identification of thymic tissue may require extensive sampling.
- When cysts become infected, the surface epithelium may be replaced by fibrous tissue.
- Secondary alterations may often include the presence of foreign body giant cell reaction and/or cholesterol granulomas.
- Due to the fact that the third and fourth branchial pouches give rise to the inferior and superior parathyroid glands, respectively, parathyroid parenchyma may be found in thymic cysts.

Differential Diagnosis

- Branchial cleft cyst:
 - Clinical and histopathologic differences should allow for differentiating a branchial cleft cyst from a thymic cyst.

- Cervical thymic cysts and branchial cleft cysts tend to occur in the anterior cervical triangle.
- In contrast to cervical thymic cysts, which occur typically in the first decade of life, have a slight female predilection, generally are not associated with sinuses or fistulas, and have thymic tissue in their walls
- Branchial cleft cysts tend to occur in the third decade of life, have equal gender predilection, commonly are associated with cysts and fistulas, and have lymphoid tissue in their wall.

Treatment and Prognosis

- Treatment for cervical thymic cyst is simple surgical excision, which is curative.
- Cervical thymic cysts have no potential to undergo malignant transformation, which is not true of mediastinal thymic cysts.

BRONCHOGENIC CYST (Fig. 12-6)

Definition: Bronchogenic cysts originate from buds or diverticula that separate from the foregut during the formation of the tracheobronchial tree:

- The majority of bronchogenic cysts are found in the mediastinum or in the lungs and are referred to as mediastinal bronchogenic cysts.
- Bronchogenic cysts may occur outside the mediastinum, with the skin or subcutaneous tissue representing the most common site of occurrence (referred to as cutaneous bronchogenic cysts), particularly near the suprasternal notch (manubrium sterni), and much less often in the lower neck or shoulder.

Synonym: Bronchial cyst

Fig. 12-6. Bronchogenic cyst.

Lower neck cystic lesion lined by ciliated respiratory epithelium; bronchial (sero mucous) glands, as well as cartilage and smooth muscle are present.

Clinical

- No gender predilection; occur over a wide age range from birth to the sixth decade of life:
 - Average age of occurrence is in the third and fourth decades
- In the very young, mediastinal bronchogenic cysts may produce life-threatening respiratory distress with stridor and airway obstruction.
- In adults, mediastinal bronchogenic cysts are usually asymptomatic and identified by routine chest x-rays.
- Radiology:
 - Solitary, smooth, round-to-ovoid cyst in the mediastinum (middle, posterior, or superior) closely associated with the trachea or major bronchi
 - An occasional example may be found within the wall of the bronchus, trachea, or esophagus, attached to the pericardium, or even within the outflow tract of the right ventricle or the interatrial septum.
 - Rare examples have been reported in the pharyngeal region or lateral neck.
- Rare examples of congenital anomalies have been reported in association with mediastinal bronchogenic cyst, but typically these lesions are not associated with developmental anomalies.

Pathology

Gross

- Cysts are typically unilocular and thin-walled and may measure up to 15 cm in greatest dimension.
- Cysts have a smooth-appearing lining that on occasion may be trabeculated; the cyst content varies from serous fluid to serosanguineous to mucoid and, if infected, purulent material.

Microscopic

- Cyst lining usually is a ciliated respiratory epithelium and bronchial (mucous) glands, as well as cartilage and smooth muscle are usually present.
- Squamous metaplasia of the surface epithelium may be identified.

Differential Diagnosis

- Branchial cleft cyst
- Thyroglossal duct cyst
- Dermoid cyst
- Teratoma

NOTE:

- Presence of (sero)mucous glands, cartilage, and smooth muscle in bronchogenic cyst allows differentiation from a branchial cleft cyst and thyroglossal duct cyst, in which these components are not found.

- Presence of thyroid follicles in a thyroglossal duct cyst would assist in differentiating it from a bronchogenic cyst.
- Absence of hair and relative absence of squamous epithelium in bronchogenic cyst would assist in differentiating it from a dermoid cyst.
- Teratomas contain an array of tissue types that are not present in bronchogenic cysts.

Treatment and Prognosis

- Excision of the cyst via an external approach generally is curative.
- Malignant transformation of cervical (and mediastinal) bronchogenic cysts has not been described to date.

DERMOID CYST (Fig. 12-7)

Definition: Benign developmental cystic anomaly originating from ectoderm and mesoderm but not endoderm.

Clinical

- Head and neck are fairly common sites of occurrence for dermoid cysts, accounting for approximately 34% of all dermoid cysts.
- No gender predilection; may occur over a wide age range but are most common in the first decade of life
- In the head and neck, dermoid cysts are predominantly subcutaneous lesions but may occur in other (mucosal) sites:
 - Among the more common sites of occurrence in the head and neck are the orbit, oral cavity, and nasal cavity.

Fig. 12-7. Dermoid cyst.

Cyst is lined by stratified squamous epithelium with cutaneous adnexal structures (e.g., sebaceous glands) in the fibroconnective tissue wall. The adnexal structures may also include eccrine glands or apocrine glands (not shown), which are features not found in epidermoid cysts.

- Less common sites of occurrence include the mandible, maxilla, middle ear, neck (midline or near midline), upper neck, and near the thyroid cartilage or associated with the thyroid gland, suggesting a thyroid nodule.
- Dermoid cysts are slow-growing and not associated with pain.

Pathology

Gross

- Thin-walled cysts containing gray-white friable material and range in size from a few millimeters to 12 cm in greatest dimension; internal aspect of has a smooth lining.

Histology

- Dermoid cysts are lined by stratified squamous epithelium with cutaneous adnexal structures (e.g., hair shafts, sebaceous glands, eccrine glands, or apocrine glands) in the fibroconnective tissue wall.

- Cyst content may include keratin or sebaceous material.
- Dermoid cysts may rupture, resulting in a (florid) foreign body giant cell reaction.

Differential Diagnosis

- Epidermal inclusion cyst:
 - Like dermoid cysts, epidermal inclusion cysts are lined by stratified squamous epithelium and are filled with keratin.
 - In contrast to dermoid cysts, the epidermal inclusion cysts lack adnexal structures in the cyst wall.
- Teratomas:
 - Represent true neoplasms composed of tissues from all three germ layers

Treatment and Prognosis

- Simple surgical excision is the preferred treatment and is curative.

INFECTIOUS DISEASES OF THE NECK

- Infections of the oral cavity, nasopharynx, oropharynx, and cervical neck include fungal, viral, bacterial, mycobacterial, protozoal, and other infectious agents.
- The breadth of infectious diseases of these sites is extensive, and this section focuses on select infectious diseases of these anatomic sites.

MYCOBACTERIAL AND OTHER GRANULOMATOUS DISEASES

Mycobacterial Infections

Definition: Infectious disease caused by *Mycobacterium*, a microorganism classified in the order Actinomycetales and the family Mycobacteriaceae.

- Mycobacteria include:
 - *Mycobacterium tuberculosis*:
 - Strict aerobic bacillus measuring from 1 to 4 μm in length
 - Microorganism identification requires special stains and is based on the capability of forming stable mycolate complexes with certain aryl methane dyes resisting decolorization by acid alcohol referred to as acid-fastness
 - Tubercle bacilli that make up the *M. tuberculosis* complex (MTBC) and are the

etiologic agents in human tuberculosis include:

- *Mycobacterium tuberculosis*, *Mycobacterium bovis*, *Mycobacterium bovis* bacille Calmette-Guérin (BCG), *Mycobacterium caprae*, *Mycobacterium pinnipedii*, *Mycobacterium africanum*, *Mycobacterium microti*, *Mycobacterium canettii*.
- Nontuberculous (“atypical”) mycobacteria are also referred to as mycobacterium other than *tuberculosis* (MOTT):
 - Some of the nontuberculous mycobacteria include *M. avium-intracellulare*, *M. scrofulaceum*, *M. kansasii*, and *M. ulcerans*.

Clinical

- Mycobacterial infection of the head and neck is relatively uncommon.
 - Overall the incidence of *Mycobacterium tuberculosis* has decreased over the past five decades:
 - Of reported cases of extrapulmonary mycobacterial infections, 12% affect head and neck sites.
 - With the advent of the acquired immunodeficiency syndrome (AIDS) associated with immunocompromised conditions, there has been an increased incidence of infection by mycobacteria, especially caused by the nontuberculous (“atypical”) mycobacteria.

- Nontuberculous (“atypical”) mycobacteria (MOTT):
 - Only some are human pathogens.
 - In the immune-competent patient, the nontuberculous mycobacteria do not cause pulmonary disease but often cause localized disease such as lymphadenitis (e.g., scrofula, see below) or a subcutaneous infection.
 - In the immune-compromised patient these microorganisms cause pneumonia and potentially disseminated (systemic) disease.
 - In the head and neck, all sites may be involved but infection usually involves the lymph nodes; less often involvement may include the tonsils, pharynx, oral cavity, sinonasal region, larynx, salivary glands, middle ear, and temporal bone.
 - Head and neck involvement may result as a complication of pulmonary involvement (direct infection via expectoration of infected sputum), via hematogenous or lymphatic spread, or as an isolated occurrence as a primary upper aerodigestive tract infection.
 - May occur in patients with coexisting carcinoma (e.g., squamous cell carcinoma)
 - Symptoms vary according to the site(s) infected and include a neck mass (cervical adenopathy), sore throat, nasal obstruction, hoarseness, dysphagia.
 - Clinical work-up in suspected cases includes chest x-ray, tuberculin skin test, microbiologic cultures, and molecular diagnostics:
 - Reference (“gold”) standard is microbiologic cultures and identification on specific media:
 - Allows for testing of drug susceptibility
 - Depending on the media used, incubation (i.e., growth) takes from 2 to as long as 6 to 10 weeks (or longer), potentially resulting in delay in diagnosis and treatment.
 - Media used in testing for tuberculosis includes:
 - Solid media includes Löwenstein-Jensen
 - Liquid media include the nonradiometric BACTEC Mycobacteria Growth Indicator Tube 960 (MGIT) system, which has replaced radiometric BACTEC 460 system susceptibility testing.
 - Liquid media-based culture is more sensitive and growth is more rapid as compared with solid media:
 - In liquid media growth may occur from 1 to 3 weeks as compared with 3 to 8 weeks for solid media.
 - Most rapid method for diagnosis of tuberculosis is the nucleic acid amplification test for direct detection of MTBC in clinical specimens (e.g., sputum, fluids, and tissue [formalin-fixed paraffin embedded]):
 - Sensitive as cultures but requires significantly less time to perform and result (4 to 5 hours)
 - Allows for more rapid diagnosis but these tests do not differentiate species in MTBC
 - Can detect as few as 10 organisms in clinical specimens as compared with more than 10,000 organisms required for positive identification on smears
 - Available tests include Amplified Mycobacterium Tuberculosis Direct Test (Gen-Probe Inc.) and AMPLICOR Mycobacterium Tuberculosis Test (Roche Diagnostics).
 - Sensitivity of nucleic acid amplification tests generally slightly lower for nonrespiratory specimens but useful in the diagnosis of extra-pulmonary tuberculosis
 - Susceptibility testing:
 - Once an isolate is available, drug susceptibility testing is performed.
 - New diagnostics using liquid media-based cultures are more sensitive and growth is more rapid as compared with solid media.
 - For MTBC, the initial isolate from every patient should be tested to all primary drugs:
 - Agar proportion is the standard method of testing susceptibility of MTBC to antituberculosis agents:
 - Isolates showing greater than 1% resistance to a single concentration of drug considered resistant to that drug
 - Liquid-based system allowing for quicker turnaround time for results as compared to agar is recommended:
 - Results available 5 to 7 days after bottles inoculated with MTBC
 - Molecular methods, including polymerase chain reaction, developed for rapid detection of mutations known to be associated with drug resistance including multidrug-resistant organisms (MDR-TB) and extensively drug-resistant tuberculosis (XDR-TB).
- Lupus vulgaris:
 - Represents mucocutaneous lesions of secondary tuberculosis
 - Results from hematogenous or lymphatic spread of disease
 - Nose and cheeks are the most common sites of occurrence.
 - May be ulcerative and destructive:
 - Destructive nature thought to be due to hypersensitivity to the microorganisms in patients with strong immune responses
 - Association in approximately 40% of cases with upper aerodigestive tract lesions and cervical lymphadenitis
 - Healing may result in scarring and deformity of involved region.

Fig. 12-8. *Mycobacterium tuberculosis*.

A, The histologic hallmark of mycobacterial disease in the presence of normal immune status includes the presence of caseating (necrotizing) granulomatous inflammation characterized by well-formed granulomas including central areas of necrosis surrounded by histiocytes and multinucleated giant cells. **B**, By acid-fast bacilli (AFB) stain the microorganisms appear beaded with a red color. The microorganisms may be difficult to identify and may be located in necrotic foci and/or within multinucleated giant cells.

Pathology (Fig. 12-8)

Histology

- In the presence of normal immune status, changes include caseating (necrotizing) granulomatous inflammation in which the granulomas are:
 - Well formed
 - Surrounded by histiocytes and multinucleated giant cells
 - Composed of central areas of necrosis
- May also include noncaseating type of granuloma formation
- Histochemistry:

NOTE: Microorganisms are often extremely difficult to identify and may defy detection despite an extensive and diligent effort:

 - Identification of microorganisms requires special stains and is based on the capability of forming stable mycolate complexes with certain aryl methane dyes referred to as acid-fastness
 - Depending on the stain (acid-fast bacilli [AFB], Ziehl-Neelsen), the microorganisms when identified appear beaded with a red or purple color
 - May be located in necrotic foci and/or within giant cells

Differential Diagnosis

- Sarcoidosis
- Other infectious necrotizing granulomatous diseases

Treatment and Prognosis

- The cornerstone for treatment is multidrug (antituberculous) therapy:
 - First line:
 - Isoniazid, rifampicin, ethambutol, and pyrazinamide
 - Duration of 6 months:
 - 2-month intensive therapy with the four drugs
 - 4-month continued therapy with isoniazid, rifampicin
 - Second line:
 - Streptomycin, ethionamide, kanamycin, capreomycin, ofloxacin, rifabutin
- Among new cases of tuberculosis, approximately 5% worldwide are due to multidrug-resistant organisms (MDR-TB) defined as tubercle bacilli resistant to isoniazid and rifampin.
- Mismanagement of drugs used to treat MDR-TB can result in extensively drug-resistant tuberculosis (XDR-TB) defined as MDR-TB plus resistance to any fluoroquinolone and any second-line injectable anti-tuberculosis agent.
- In association with AIDS, therapy is lifelong.

Scrofula (Fig. 12-9)

Definition: Cervical lymph node involvement by mycobacteria is referred to as scrofula.

Synonym: Scrofulous gumma

Fig. 12-9. Mycobacterial involvement of cervical lymph nodes (scrofula).

A, Unilateral, firm, red neck mass with focal ulceration of the skin. **B**, Extensive cutaneous ulceration. **C**, Histologic appearance includes replacement of the nodal architecture by caseating granulomas characterized by central necrosis surrounded by histiocytes and giant cells. **D**, Mycobacteria are extremely difficult to identify and require the aid of special histochemical stains (acid-fast bacilli [AFB] stain) with the microorganism appearing as a slender, beaded, red/purple rod seen here in a multinucleated giant cell.

Clinical

- More common in women than men; may occur over a wide age range but primarily affects children
- Most commonly involves high cervical lymph nodes in the region of the submandibular gland
 - Periparotid, periauricular, and submental lymph nodes may be involved but are much less often affected.
- Usually presents as a unilateral neck mass when caused by nontuberculous mycobacteria; bilateral involvement generally is related to systemic involvement caused by dissemination of *M. tuberculosis*
- Patients are afebrile.
- Causative microorganism may include *M. tuberculosis* but most commonly caused by nontuberculous mycobacteria (*M. scrofulaceum*, *M. avium-intracellulare*, *M. kansasii*)
- Although scrofula may be an isolated infection, it may also be the initial presentation in patients with pulmonary disease.
- May occur in patients with immune reconstitution inflammatory syndrome (IRIS):
 - IRIS represents a cohort of HIV-infected patients receiving combined antiretroviral therapy (cART).

Pathology

Gross

- Involved lymph nodes are enlarged and firm.
- Mucosal involvement appears as a granular exudate with or without associated ulceration; cutaneous ulceration may occur.

Histology

- Irrespective of the causative microorganism, the histologic picture of mycobacterial infection is the same.
- In the immune-competent host, the histologic hallmark of mycobacterial infection regardless of the causative microorganism is caseating (necrotizing) granulomatous inflammation characterized by:
 - Central necrosis surrounded by histiocytes and giant cells
- In up to 25% of cases of nontuberculous mycobacterial infections, a caseating granulomatous inflammatory response is not present.
- In the immune-compromised patient the typical caseating granulomatous inflammatory response may not be present; rather, diffuse sheets of foamy histiocytes are present within which are AFB-positive microorganisms.
- Histochemistry:

NOTE: Microorganisms are often extremely difficult to identify and may defy detection despite an extensive and diligent effort:

- Identification of microorganisms requires special stains and is based on the capability of forming stable mycolate complexes with certain aryl methane dyes referred to as acid-fastness.
- Depending on the stain (acid-fast bacilli [AFB], Ziehl-Neelsen), the microorganisms, when identified, appear beaded, showing a red or purple color.
- Cytogenetic and molecular genetics:
 - In situ hybridization and polymerase chain reaction have improved the diagnostic identification of mycobacterial organisms and, along with cultures, allow for differentiating *M. tuberculosis* from nontuberculous mycobacteria.

Differential Diagnosis

- Sarcoidosis
- Cat scratch disease

Treatment and Prognosis

- Treatment for scrofula caused by nontuberculous mycobacteria is surgical excision, which is considered curative:
 - Nontuberculous mycobacteria are nonresponsive to anti-mycobacterial tuberculosis medications.
- For infection caused by *M. tuberculosis*, treatment consists of antituberculous chemotherapy, including:
 - Isoniazid, streptomycin, or rifampin

Mycobacterial Spindle Cell Pseudotumor (Fig. 12-10)

Definition: Pseudoneoplastic spindle cell proliferation almost exclusively occurring in HIV-infected patients.

Synonyms: Mycobacterial pseudotumor; *M. avium-intracellulare* pseudotumor; spindled nontuberculous mycobacteriosis; histoid mycobacteriosis

Clinical

- Uncommon lesion
- No gender predilection; occurs over wide age range
- Almost always found in immune-compromised individual due to:
 - AIDS/HIV-positive patients
 - Patients receiving immunosuppressive therapy, including steroids
- Causative microorganism is *M. avium-intracellulare*
- Sites of involvement includes lymph nodes, as well as extranodal sites such as skin, spleen, brain, and bone marrow:
 - Rarely may occur in mucosal sites of the upper aerodigestive tract
- Presentation includes subcutaneous firm nodule or lymphadenopathy.

Fig. 12-10. Mycobacterial spindle cell pseudotumor.

A, Immunocompromised patient presenting with subcutaneous firm nodule. **B** and **C**, Cellular proliferation composed of bland-appearing, spindle-shaped cells in a storiform pattern with multinucleated giant cells and foamy histiocytes are not present. **D**, Special stains for mycobacteria (AFB) show the presence of numerous AFB-positive microorganisms within the cytoplasm of the spindle cells.

Pathology

Histology

- Cellular proliferation composed of bland-appearing, spindle-shaped cells in a storiform pattern.
- Multinucleated giant cells and foamy histiocytes are not present.
- Partial or complete effacement of nodal architecture
- Histochemistry:
 - Special stains for mycobacteria, including AFB and Ziehl-Neelsen, show the presence of numerous AFB-positive organisms within the cytoplasm of the spindle cells.
- Immunohistochemistry:
 - Spindle cells are CD68, lysozyme, α -antichymotrypsin, and vimentin positive.

- Based on the CD68 reactivity the spindle cells represent macrophages.
- S100 protein, desmin, and muscle-specific actin may be positive.
- CD31 and CD34 negative
- Cytogenetics and molecular genetics:
 - Polymerase chain reaction assists in identifying mycobacteria.

Differential Diagnosis

- Kaposi sarcoma:
 - May occur concomitantly (in same lymph node) as mycobacterial spindle cell tumor
 - Morphologic features that favor Kaposi sarcoma over mycobacterial spindle cell tumor include:
 - Prominent fascicular arrangement of spindle cells and slit-like spaces

- Absence of granular, acidophilic cytoplasm
- Presence of increased mitotic activity
- Presence of hyaline globules and extravasated red cells
- Immunohistochemical features seen in the spindle cells of Kaposi sarcoma that assist in differentiating it from mycobacterial spindle cell tumor include:
 - Reactivity for human herpesvirus-8 (HHV-8), also referred to as Kaposi sarcoma–associated herpesvirus (KSHV)
 - Reactivity for CD31 and CD34
 - Absence of CD68 and S100 protein, as well as muscle-specific actin and desmin
- Fibrohistiocytic tumor(s)
- Hodgkin disease, nodular sclerosing

Treatment and Prognosis

- Treatment guidelines are based on the species of mycobacteria and susceptibility testing of the isolate that, in some cases, would be modified because of the immune status of the patient or other concurrent therapy.
- If no isolate is obtained, recommendation would be to treat for tuberculosis:
 - Specific drugs chosen would depend on the likelihood of drug resistance based on demographic/epidemiologic factors.

Cervicofacial Actinomycosis

(Fig. 12-11)

Definition: Chronic granulomatous and suppurative disease caused by gram-positive, microaerophilic, and anaerobic bacteria, the most common isolate in humans causing disease being *Actinomyces israelii*:

- Actinomyces are endogenous saprophytic organisms in the oral cavity and tonsil.
- Actinomyces are often seen within tonsillar crypts, which represent a saprophyte and are unaccompanied by an inflammatory response.
- Disease is classified according to the anatomic site involved and includes cervicofacial, abdominal, and pulmonary.

Cervicofacial Actinomycosis

Clinical

- Cervicofacial actinomycosis is the most common form of disease and is thought to arise secondary to dental manipulation and/or trauma.
- No gender predilection; occurs in all age groups
- Neck and area around the angle of the mandible are the most common sites of occurrence; however,

clinical infection can occur anywhere in the head and neck.

- Most common symptom is that of a painless, slowly enlarging, indurated mass with or without suppuration; skin overlying the lesion has a characteristic purple color from which a draining sinus may be seen; fistulization is not uncommon.
- A definitive diagnosis is made bacteriologically; however, the organisms are difficult to culture.

Pathology

Histology

- Granulomatous reaction with central accumulation of polymorphonuclear leukocytes (abscess formation) and necrosis is identified.
- Within the abscess and enveloped by the neutrophils, microorganism colonies are seen:
 - Microorganisms form a characteristic appearance referred to as sulfur granules.
 - Granules are lobular, deep purple, and composed of a central meshwork of filaments that typically have eosinophilic club-shaped ends.
 - Sulfur granules can be identified in pus.
- Diagnosis can be made by fine-needle aspiration biopsy:
 - Smears and cell blocks of the aspirate may show characteristic colonies (sulfur granules) of actinomyces.
- Histochemistry:
 - Microorganisms stain best with gram and Gomori methenamine silver (GMS) stains.

Differential Diagnosis

- *Nocardia* infection

Treatment and Prognosis

- Intravenous penicillin G followed by oral penicillin is the preferred treatment.
- Patients allergic to penicillin can be given tetracycline.
- Prognosis is good if treated early.
- Osteomyelitis of the jaw is the most common complication; once infection reaches bone, tissue destruction may be extensive and involvement of the cranium, meninges, and brain may occur with lethal implications.

Sarcoidosis (Fig. 12-12)

Definition: Multisystem chronic granulomatous disease of unknown cause.

Clinical

- No gender predilection; occurs in all age groups but seen most commonly in young adults

Fig. 12-11. Cervicofacial actinomycosis.

A, Indurated, suppurative neck mass around the angle of the mandible; the skin overlying the lesion has a characteristic purple color. **B**, Cervical lymph node with central accumulation of polymorphonuclear leukocytes (abscess formation) and necrosis. **C**, Within the abscess and enveloped by the neutrophils, actinomycotic colonies are seen with a characteristic appearance referred to as “sulfur granules”; the granules are lobular, deep purple, and composed of a central meshwork of filaments, which typically have eosinophilic club-shaped ends. **D**, Microorganisms stain best with Gram (*left*) and Gomori methenamine silver (GMS) stains (*right*).

- Any organ system may be involved; the most common include the lungs, skin, and lymph nodes.
- Most common clinical presentation is with fever, weight loss, and hilar adenopathy
- Isolated extranodal head and neck involvement occurs only in a small percentage of cases and includes:
 - Pharynx and tonsils
 - Ear and temporal bones
 - Sinonasal region, salivary glands, and larynx
- Site-specific involvement may occur as an isolated phenomenon or may coexist with systemic disease.
- Otolaryngologic symptoms vary according to site and include:
 - Cervical adenopathy, pharyngotonsillitis with tonsillar enlargement, airway obstruction, nasal discharge, epistaxis
 - Salivary gland involvement may clinically simulate Sjögren syndrome with salivary gland enlargement, xerostomia, and xerophthalmia
 - Involvement of the parotid gland and uveal tract referred to as uveoparotid fever or Heerfordt syndrome may present with facial nerve paralysis.

Fig. 12-12. Sarcoidosis.

A, Oral cavity (soft palate) sarcoidosis appearing as multiple, irregular nodules with a cobblestone appearance. **B** through **D**, Histologic picture of sarcoidosis irrespective of location includes multiple well-formed, noncaseating granulomas consisting of nodules of epithelioid histiocytes surrounded by a mixed inflammatory infiltrate; Langhans-type giant cells are seen in some of the nodules. A diagnosis of sarcoidosis is suggested/established following exclusion of a possible infectious cause; to this end, special stains for microorganisms are negative.

- No laboratory findings specific for or diagnostic of sarcoidosis:
 - Cutaneous anergy to skin test antigens (Kveim test) is positive in 60% to 85% of patients.
 - Elevated angiotensin converting enzyme (ACE):
 - Used as a marker for sarcoid disease activity
 - Not unique to sarcoidosis but can be elevated in other diseases including diabetes, hyperthyroidism, multiple sclerosis, asthma, nephrotic syndrome, others
 - ACE inhibitors used with varying success in the treatment of patients with sarcoidosis
- Cause remains unknown, but there is increasing evidence of finding mycobacterial DNA by polymerase chain reaction in sarcoid granulomas.

Pathology

Histology

- Presence of multiple noncaseating granulomas consisting of well-formed nodular foci composed of epithelioid histiocytes surrounded by a mixed inflammatory infiltrate:
 - Typically there is no associated caseation
 - Occasionally caseating granulomas may occur in sarcoidosis:

- Necrosis is absent but some examples, especially extranodal lesions, may have small foci of centrally located necrosis.
- Langerhans-type giant cells may be present.
- Intracytoplasmic inclusions including star-shaped and/or calcific laminated bodies called asteroid and Schaumann bodies, respectively, can be seen.
- Calcium oxalate crystals may be present in the cytoplasm of giant cells.
- Histochemistry:
 - All special stains for microorganisms are negative.
- Diagnosis of sarcoidosis is generally one of exclusion and is made by correlation of clinical, radiologic, and pathologic findings; although the pathologic features are characteristic, they are not specific for sarcoidosis and the diagnosis of sarcoidosis can be rendered only in the absence of identifying an infectious agent.
- In the majority of cases, a history of exposure to a cat can be obtained and the primary inoculation site identified typically seen from 7 to 12 days following contact.
- Primarily occurs in immunocompetent individuals:
 - May occur as localized disease in solid organ transplant recipients
- Symptoms include enlarged and often tender lymph nodes with potential involvement of the submental, submandibular, cervical, occipital, and supraclavicular lymph nodes as well as cervical lymph nodes in the anterior and posterior triangles of the neck:
 - Obstruction and inflammation may be seen in salivary glands with involved lymph nodes.
- Constitutional symptoms include low-grade fever, malaise, myalgias, headaches, and anorexia; less common manifestations/complications include granulomatous conjunctivitis (Parinaud oculoglandular syndrome), thrombocytopenic purpura, encephalitis, osteomyelitis, and hepatosplenomegaly. A positive skin test can confirm the diagnosis.
- Cutaneous lesions appear as a red papule, which may become crusted or pustular.

Differential Diagnosis

- Noncaseating granulomatous inflammation can be seen in:
 - Tuberculosis (typical and atypical), fungal diseases, leprosy, cat scratch disease, and many other infectious diseases
- Noninfectious diseases of the upper aerodigestive tract (e.g., Crohn disease) may also be associated with noncaseating granulomatous inflammation.

Treatment and Prognosis

- Treatment for symptomatic sarcoidosis is with corticosteroid therapy.
- Prognosis is generally good, with up to 70% of patients improving or remaining stable following therapy.
- Advanced multisystem disease leading to extensive pulmonary involvement and respiratory failure may occur but is seen in only a small percentage of cases.

BACTERIAL DISEASES

Cat Scratch Disease (Fig. 12-13)

Definition: Infectious disease is caused by a pleomorphic, gram-negative bacterium, *Bartonella henselae*, resulting in lymphadenopathy.

Clinical

- No gender predilection; occurs in all ages
- Mode of transmission is by direct contact from a cat scratch, bite, or lick through a skin break:
 - There is no evidence to support transmission from human to human.
 - The infected cat is not ill and appears to be infectious for only a limited time.

Pathology

- Changes in the affected lymph node vary with time:
 - Early lesions show:
 - Follicular hyperplasia and histiocytic proliferation
 - Intermediate stage lesions show:
 - Granulomatous inflammation
 - Late lesions show:
 - Abscess formation
 - Appearance of the abscess includes a central area of necrosis with a stellate pattern and an admixture of polymorphonuclear leukocytes surrounded by palisading of histiocytes; this pattern is suggestive of the diagnosis
 - Nodal sinuses are packed with monocytoid B-cells.
- Skin lesions show necrotic areas within the dermis surrounded by histiocytes.
- Histochemistry:
 - Cat scratch bacilli can be identified by Warthin-Starry stain and appear as extracellular pleomorphic coccobacilli.
 - Staining and culturing for acid-fast microorganisms are negative.

Differential Diagnosis

- Toxoplasmosis
- Lymphogranuloma venereum

Treatment and Prognosis

- Treatment is supportive and includes analgesics and warm compresses.

Fig. 12-13. Cat scratch disease.

A, Woman presenting with enlarged (and tender) lymph nodes. **B**, Characteristic but not pathognomonic appearance of the abscess composed of a central area of necrosis with a stellate pattern admixed with polymorphonuclear leukocytes surrounded by palisading of histiocytes. **C**, Causative bacterium (*Bartonella henselae*) identified by Warthin-Starry stain appear as extracellular pleomorphic coccobacilli.

- Self-limiting disease that typically runs its course within a few months
- In cases with suppuration, needle aspiration may relieve pain; incision and drainage may produce sinus tract inflammation.
- Antibiotic therapy appears to be of little benefit.

Bacillary Angiomatosis (BA) (Fig. 12-14)

Definition: Pseudoneoplastic capillary proliferative lesion that occurs as a complication of HIV infection and usually presents as a cutaneous vascular lesion and is caused by an opportunistic bacterial infection belonging to *Rochalimaea* species (*R. henselae*) as well as by *Bartonella quintana*.

Synonyms: Epithelioid angiomatosis; epithelioid hemangioma-like vascular proliferation

Clinical

- No gender predilection; occurs in over a wide age range
- Most commonly presents as a cutaneous lesion commonly associated with systemic symptoms, including fever, chills, weight loss, and night sweats
- Clinically, lesions are similar in appearance to lobular capillary hemangioma (pyogenic granuloma) and Kaposi sarcoma and characterized by the presence of multiple erythematous papules with or without crusting.
- May involve other organs sites including lymph nodes, spleen, and liver, as well as mucosal sites of the upper respiratory tract and conjunctiva
- Occurs most often in immunocompromised patients but may occur in patients with intact immune system
 - May occur in association with Kaposi sarcoma
 - May occur in solid organ transplant recipients (adults and pediatric patients)

Fig. 12-14. Bacillary angiomatosis.

A, Lymph node replacement by well-circumscribed lobular proliferations. **B**, Small capillaries are arranged around ectatic vessels, which are lined by prominent appearing endothelial cells; fibrotic stroma is seen separating the lobular proliferation. Scattered neutrophils and neutrophilic debris can be seen adjacent to the capillary proliferation. **C, Left**, Vascular proliferation with prominent endothelial cells and scattered neutrophils associated with granular-appearing areas; **right**, Warthin-Starry staining shows the granular material to contain bacteria; bacteria are interstitially located.

- Laboratory diagnosis:
 - Serologic demonstration of antibodies by direct immunofluorescence and enzyme immunoassay
 - Proteomic analysis with identification of immunoreactive antigens found to be useful for an improved *Bartonella*-specific serodiagnosis.

Pathology

Gross

- Varies widely from cutaneous erythematous papules to mushroom-shaped papules and nodules to deep-seated rounded lesions without change in skin color.
- Exceptionally, may appear as a mucosal-based, erythematous nodular proliferation

Histology

- Regardless of its clinical presentation, the histologic features are the same and include a well-circumscribed

lobular capillary proliferation with overall features similar to those seen in lobular capillary hemangioma.

- Small capillaries are arranged around ectatic vessels, which are lined by prominent-appearing endothelial cells.
- Cytologic atypia, mitotic figures, and necrosis are not usually present but occasionally may be seen.
- Solid areas may be present and may obscure the vascular proliferation.
- A variable edematous, mucinous, or fibrotic stroma is seen separating the lobular proliferation.
- An important histologic feature in BA is the presence of neutrophils and neutrophilic debris adjacent to the capillary proliferation; associated with the neutrophils are granular clumps.
- BA typically lacks spindled cells, interconnecting vascular channels, or hyaline globules.

- Overlying epithelium may be ulcerated, thinned, or show pseudoepitheliomatous hyperplasia.
- Histochemical stains:
 - Warthin-Starry staining shows the granular material to contain bacteria; bacteria are interstitially located.
- Immunohistochemistry:
 - HHV-8 negative

Differential Diagnosis

- Lobular capillary hemangioma (pyogenic granuloma)
- Epithelioid hemangioma
- Angiosarcoma
- Kaposi sarcoma:
 - Presence of granular material, neutrophils, and neutrophilic debris and the absence of cytologic atypia, ramifying and interconnecting vascular channels, necrosis, mitotic activity, and hyaline globules assist in differentiating BA from these other vascular lesions
 - Presence of HHV-8 immunoreactivity
- Verruga peruana, another vascular proliferation process caused by an infectious agent (*Bartonella bacilliformis*), is endemic to Peru. The presence of characteristic inclusions, referred to as Rocha-Lima inclusions, allows for differentiation.

Treatment and Prognosis

- Treatment for BA is directed at the causative microorganism:
 - Full-dose erythromycin is effective, often resulting in the resolution of the lesions.
- If left untreated, BA is progressive and potentially life threatening.

FUNGAL, VIRAL, AND PROTOZOAL DISEASES

- Fungal, viral, and protozoal diseases of the cervical neck are rare.
- HPV-associated and EBV-associated carcinomas originating from the oropharynx (tonsil, base of tongue) and nasopharynx, respectively, may metastasize to cervical neck lymph nodes (see Section 3, The Pharynx, and Chapter 13 for more complete discussion of these cancer types).

Neoplasms of the Neck

CLASSIFICATION OF NEOPLASMS OF THE NECK

BOX 13-1 Classification of Neoplastic Lesions of the Neck

Benign

Mesenchymal/Neuroectodermal

- Fibromatosis
- Nodular fasciitis
- Paraganglioma
- Lipomas
- Nerve sheath tumors
- Rhabdomyoma
- Vascular neoplasms (e.g., angiofibroma, hemangioma, lymphangioma)
- Lymphatic malformation (lymphangiomas)
- Others

Malignant

Hematolymphoid Malignant Neoplasms

- Non-Hodgkin lymphomas
- Hodgkin lymphoma
- Others

Sarcomas

- Malignant peripheral nerve sheath tumors
- Rhabdomyosarcoma
- Leiomyosarcoma
- Liposarcoma
- Angiosarcoma
- Synovial sarcoma
- Others

Metastatic Cervical Carcinoma with an Unknown Primary Tumor (MCCUP)

Secondary Neoplasms

tract, pharynx, salivary glands, and thyroid gland.

- The most common neoplastic lesions of the neck are metastatic tumors to cervical neck lymph nodes, including those originating from head and neck sites (most common) and those originating from non-head and neck sites (less common).
- Metastatic carcinomas originating from head and neck sites include:
 - Squamous cell carcinoma and variants thereof (most common)
 - Adenocarcinomas (less common)
- Metastatic carcinomas occurring in the absence of a known primary carcinoma are referred to as metastatic carcinoma with unknown primary (MCCUP); see later in this chapter.
 - Primary carcinoma in MCCUP may be extremely small and clinically/radiographically difficult to detect.
 - There is no correlation between the size of the primary carcinoma, which may be a few millimeters in greatest dimension, to the size of the metastasis, which may be several centimeters in greatest dimension:
 - Size differential/discrepancy between a small primary carcinoma and a large metastasis often (but not exclusively) applies to viral-associated carcinomas, including human papillomavirus (HPV) and Epstein-Barr virus (EBV) originating in the oro- and nasopharynx, respectively.
- Metastatic squamous cell carcinoma:
 - May be keratinizing or nonkeratinizing:
 - Those metastatic carcinomas that are predominantly keratinizing are usually not viral associated and are more likely to be associated with tobacco and alcohol use.
 - Those metastatic carcinomas that are predominantly nonkeratinizing are more often viral associated, including HPV-associated and EBV-associated.
 - HPV-associated metastatic carcinoma is diffusely and strongly (nuclear and cytoplasmic) immunoreactive for p16:
 - p16 staining is a surrogate marker for HPV16.
 - p16 immunoreactivity correlates to a primary oropharyngeal (tonsil, base of tongue) carcinoma.

GENERAL CONSIDERATIONS

- Primary neoplasms of the cervical neck are uncommon and include:
 - Soft tissue neoplasms (benign and malignant):
 - Fibromatosis and nodular fasciitis previously classified as nonneoplastic lesions are now recognized based on molecular analyses to be true neoplasms.
 - Hematolymphoid (non-Hodgkin and Hodgkin lymphomas):
 - The spectrum of lymphomas is extensive and beyond the scope of this book.
 - Selective lymphoma types are discussed under site-specific locations, including the sinonasal

- EBV-associated metastatic carcinoma is strongly positive (nuclear) by in situ hybridization for Epstein-Barr-encoded RNA (EBER):
 - EBER-positive metastatic carcinomas often originate from the nasopharynx.
 - Histologically, EBER-positive metastatic carcinomas may be nonkeratinizing differentiated type or nonkeratinizing undifferentiated type.
- MCCUP may be cystic and/or solid.
- Metastatic adenocarcinoma to cervical neck lymph nodes occur and may originate from a primary head and neck site or from a site other than head and neck:
 - May originate from a wide variety of head and neck sites, including but not limited to the sino-nasal tract, oral cavity, salivary glands
 - In contrast to metastatic squamous cell carcinomas of head and neck sites that may originate from an occult primary tumor, metastatic adenocarcinomas from a head and neck site typically originate from a known primary tumor and rarely from an occult primary tumor.
- Metastatic papillary thyroid carcinoma commonly metastasizes to cervical lymph nodes and may do so in the absence of a known primary thyroid carcinoma:
 - Usually, nodal metastasis of papillary thyroid carcinoma originates from the ipsilateral thyroid lobe.
 - Given its affinity for lymph-vascular spaces, nodal metastasis from a thyroid carcinoma represents papillary carcinoma even in the absence of diagnostic nuclear features.
 - Isolated (“naked”) psammoma bodies in lymph nodes are highly suggestive for nodal metastatic papillary thyroid carcinoma.
- Neuroendocrine carcinomas (NECs) may metastasize to cervical lymph nodes and may (infrequently) do so in the absence of a known primary head and neck carcinoma; such NECs may originate from the:
 - Thyroid gland, representing metastatic medullary thyroid carcinoma:
 - Associated with elevated serum calcitonin levels
 - Immunoreactive for calcitonin, neuroendocrine markers (synaptophysin, chromogranin, CD56, others), TTF1, and cytokeratins but negative for thyroglobulin
 - May originate from a nonthyroid origin, in particular the larynx:
 - Laryngeal NEC not associated with elevated serum calcitonin levels
 - Most common histologic type of laryngeal NEC is moderately differentiated NEC or atypical carcinoid.
 - Immunoreactive for calcitonin in majority of cases (>80%), neuroendocrine markers (synaptophysin, chromogranin, CD56, others), and cytokeratins but negative for thyroglobulin
- Metastatic malignant neoplasms from sites other than head and neck occur to the cervical neck lymph nodes:
 - Often metastasize to supraclavicular lymph nodes
- In the pathology report of nodal metastasis it is imperative to document presence or absence of extranodal extension (ENE):
 - Presence of ENE portends worse prognosis, including increased incidence of recurrence and distant spread.

SURGICAL SPECIMENS

Neck Dissection (Fig. 13-1)

- The neck is divided into anterior and posterior triangles by the sternocleidomastoid muscle.
- Currently, the neck is divided into six levels encompassing the complete topographic anatomy of the neck (Table 13-1), although a seventh level (level VII) may be included:
 - Level I:
 - Submental, submandibular nodes
 - Levels II through IV:
 - Upper, middle, and lower deep cervical nodes
 - Level V:
 - Posterior triangle nodes
 - Level VI:
 - Lymph nodes around thyroid gland (referred to as the central compartment)
 - Level VII:
 - Lymph nodes in the tracheoesophageal groove and superior mediastinum
- The classification of neck dissections depends on the divisions of the lymph node groups in the neck (Box 13-2).
- Types of neck dissections include:
 - Radical neck dissection:
 - Removal of all lymph node regions as well as the sternocleidomastoid muscle, internal jugular vein, and spinal accessory nerve
 - Considered to represent the standard basic procedure for cervical lymphadenopathy in patients with squamous cell carcinoma of the head and neck region
 - Modified radical neck dissection:
 - Preservation of one or more nonlymphatic structures routinely removed in the radical neck dissection

Fig. 13-1. Cervical neck anatomy and lymph node stations.

A, Cervical neck anatomic landmarks used in imaging-based nodal classification. **B**, Nodal stations delineated in a node-negative neck. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 2298, Fig. 38-9.)

- Includes removal of lymph nodes in levels I through V with preservation of one or more nonlymphatic structures, including:
 - Sternocleidomastoid muscle
 - Internal jugular vein
 - Spinal accessory nerve
- Classified into three types (Box 13-3):
 - Differences in types relate to the number of neural, vascular, and muscular structures preserved

BOX 13-2 Classification of Neck Dissections

Radical Neck Dissection

- All nodes levels I through V
- Internal jugular vein (IJV)
- Spinal accessory nerve (CN XI)
- Sternocleidomastoid (SCM)

Modified Radical Neck Dissection

- All node levels I through V
 - Type I: preserve CN XI
 - Type II: preserve CN XI and IJV
 - Type III: preserve CN XI, IJV, and SCM

Selective Neck Dissections (SND)

- Remove only selective lymph node levels, sparing all vital structures; variations include:
 - SND I-III/IV
 - SND II-IV
 - SND (II-V, postauricular, suboccipital)
 - SND VI

Extended Neck Dissection

- Removal of additional lymph node levels or groups and/or nonlymphatic structures (e.g., muscle, nerves, blood vessels) not normally removed with a radical neck dissection

Super-Selective Neck Dissection

- Complete removal of all fibrofatty contents, including lymph node along defined boundaries of one or two contiguous neck levels

CN XI, Spinal accessory nerve; IJV, internal jugular vein; SCM, sternocleidomastoid muscle.

BOX 13-3 Classification of Modified Radical Neck Dissections

Type I

- Removal of SCM and IJV
- Preservation of XI n

Type II

- Removal of SCM
- Preservation of IJV and XI n

Type III

- Preservation of all three nonlymphoid structures, including SCM, IJV, XI n

IJV, Internal jugular vein; SCM, sternocleidomastoid muscle; XI n, spinal accessory nerve.

- Selective neck dissections subdivided into:
 - Preservation of one or more lymph node groups/levels routinely removed in the radical neck dissection
 - Subdivided into:
 - Supraomohyoid:
 - Includes removal of lymph nodes in levels I through III
 - Posterolateral:
 - Includes removal of lymph nodes in levels II through V, as well as suboccipital and retroauricular lymph nodes

TABLE 13-1 Lymph Node Levels and Sublevels

Lymph Node Level	Description
I	<p>Sublevel IA: submental—lymph nodes within the triangular boundary of the anterior belly of the digastric muscles and the hyoid bone</p> <p>Sublevel IB: submandibular—lymph nodes within the boundaries of the anterior belly of the digastric muscle, stylohyoid muscle, and the body of the mandible</p>
II (upper jugular)	<p>Lymph nodes located around the upper third of the internal jugular vein and the adjacent spinal accessory nerve extending from:</p> <p>Above: level of the skull base</p> <p>Below: level of the inferior border of the hyoid bone</p> <p>Medial (anterior): stylohyoid muscle (radiologic correlate is the vertical plane defined by the posterior surface of the submandibular gland)</p> <p>Lateral (posterior): posterior border of the SCM</p> <p>Sublevel IIA: nodes located anterior (medial) to the vertical plane defined by the spinal accessory nerve</p> <p>Sublevel IIB: nodes located posterior (lateral) to the vertical plane defined by the spinal accessory nerve</p>
III (midjugular)	<p>Lymph nodes located around the middle third of the internal jugular vein extending from:</p> <p>Above: inferior border of the hyoid bone</p> <p>Below: inferior border of the cricoid cartilage</p> <p>Medial (anterior): lateral border of sternohyoid muscle</p> <p>Lateral (posterior): posterior border of the SCM</p>
IV (lower jugular)	<p>Lymph nodes located around the lower third of the internal jugular vein extending from:</p> <p>Above: inferior border of cricoid cartilage</p> <p>Below: clavicle</p>
V (posterior triangle)	<p>Lymph nodes in this group are predominantly located around the lower half of the spinal accessory nerve and the transverse cervical artery and extend from:</p> <p>Superior: apex formed by convergence of the SCM and trapezius muscle</p> <p>Inferior: clavicle</p> <p>Medial (anterior): posterior border of SCM</p> <p>Lateral (posterior): anterior border of trapezius muscle</p> <p>Sublevels include V-A and V-B separated by a horizontal plane marking the inferior border of the anterior cricoid arch:</p> <p>V-A: above this plane includes the spinal accessory lymph nodes</p> <p>V-B: below this plane includes the lymph nodes that follow the transverse cervical vessels and the supraclavicular nodes with the exception of the Virchow node, which is located in level IV</p>
VI (anterior compartment)	<p>Boundaries of this compartment include:</p> <p>Superior: hyoid bone</p> <p>Inferior: suprasternal notch</p> <p>Lateral: common carotid arteries</p> <p>Lymph nodes in this level include:</p> <ul style="list-style-type: none"> • Pretracheal and paratracheal nodes • Precricoid (delphian) nodes • Perithyroidal nodes, including those along the recurrent laryngeal nerves

SCM, Sternocleidomastoid muscle.

Modified from Houck JR, Medina JE: Management of cervical lymph nodes in squamous carcinomas of the head and neck, *Semin Surg Oncol* 11(3):228-239, 1995.

- Lateral:
 - Includes removal of lymph nodes in levels II through IV
- Anterior:
 - Includes removal of lymph nodes in level VI (pretracheal and paratracheal)
- Extended radical neck dissection:
 - Removal of additional lymph node groups or nonlymphatic structures not encompassed by radical neck dissection
 - Examples of nodal groups may include:
 - Parapharyngeal and retropharyngeal lymph nodes
 - Lymph nodes in levels VI and VII
 - Carotid artery
- Super-selective neck dissection:
 - Complete removal of all fibrofatty contents, including lymph node along defined boundaries of one or two contiguous neck levels
- Current neck staging based on a consensus between the European UICC and the American Joint Cancer Committee (AJCC) ([Table 13-2](#))
 - System uses clinical features of nodal size, number, and laterality.
 - Does not integrate imaging features, suggestive of extranodal extension

TABLE 13-2 UICC-AJCC Cervical Lymph Node Staging System

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1*	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
N2*	Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension; or in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension; or in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N2a*	Metastasis in a single ipsilateral lymph node more than 3 cm, but not more than 6 cm in greatest dimension
N2b*	Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension
N2c*	Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N3*	Metastasis in lymph node more than 6 cm in greatest dimension
M0	No distant metastasis
M1	Distant metastasis

*A designation of "U" or "L" may be used for any N stage to indicate metastasis above the lower border of the cricoid (U) or below the lower border of the cricoid (L). Similarly, clinical/radiologic ECS should be recorded as E- or E+, and histopathologic ECS should be designated as En, Em, or Eg.

BENIGN NEOPLASMS OF THE NECK

FIBROBLASTIC/ MYOFIBROBLASTIC

Aggressive Fibromatosis

(Figs. 13-2 and 13-3)

Definition: Locally aggressive, nonmetastasizing (myo) fibroblastic neoplasm characterized by locally infiltrative growth.

Synonyms: Desmoid-type fibromatosis; desmoid tumor; aggressive fibromatosis; extraabdominal desmoid, extra-abdominal fibromatosis; tumefactive fibroinflammatory tumor; inflammatory pseudotumor

General Findings

- Fibromatoses can be divided into three groups, including:
 - Sporadic:
 - Most (but not all) are extra-abdominal
 - Associated with familial adenomatous polyposis (FAP) or Gardner syndrome:
 - Most (but not all) arise intra-abdominally, especially mesentery:
 - Often occur following previous surgery (i.e., colectomy)
 - May be multifocal:
 - Multicentric or familial
- Fibromatoses can also be divided anatomically, including:
 - Extra-abdominal (60%)
 - Abdominal wall (25%)
 - Intra-abdominal (15%)

Clinical

- Identified in the head and neck in from 10% to 15% of cases; in children, this area of the body may be affected in up to 30% of cases.
- Head and neck fibromatosis occurs over a wide age range but tends to be most common in the second to fourth decades of life; there is no gender predilection:
 - Sinonasal lesions seen in children and adults but most commonly occur in the third to fourth decades of life
- Involvement of the head and neck region occurs primarily in the soft tissues of the neck:
 - Excluding the neck, the common sites of occurrence in the head and neck include the sinonasal tract, nasopharynx, and oral cavity (tongue).
 - In the sinonasal tract, the maxillary sinus is the most common site.
- Symptoms vary according to site:
 - In the neck, the clinical presentation includes enlarging painless mass:
 - In this setting lesions may involve the parotid gland.
 - In the sinonasal tract and nasopharynx, the clinical presentation includes a painless enlarging mass or nasal obstruction.
 - With progression of disease, other symptoms, including epistaxis, facial deformity, proptosis, and dysphagia, may occur.
- Radiology:
 - Often show isodense or high attenuation on post-contrast CT
 - High signal intensity on T2-weighted image

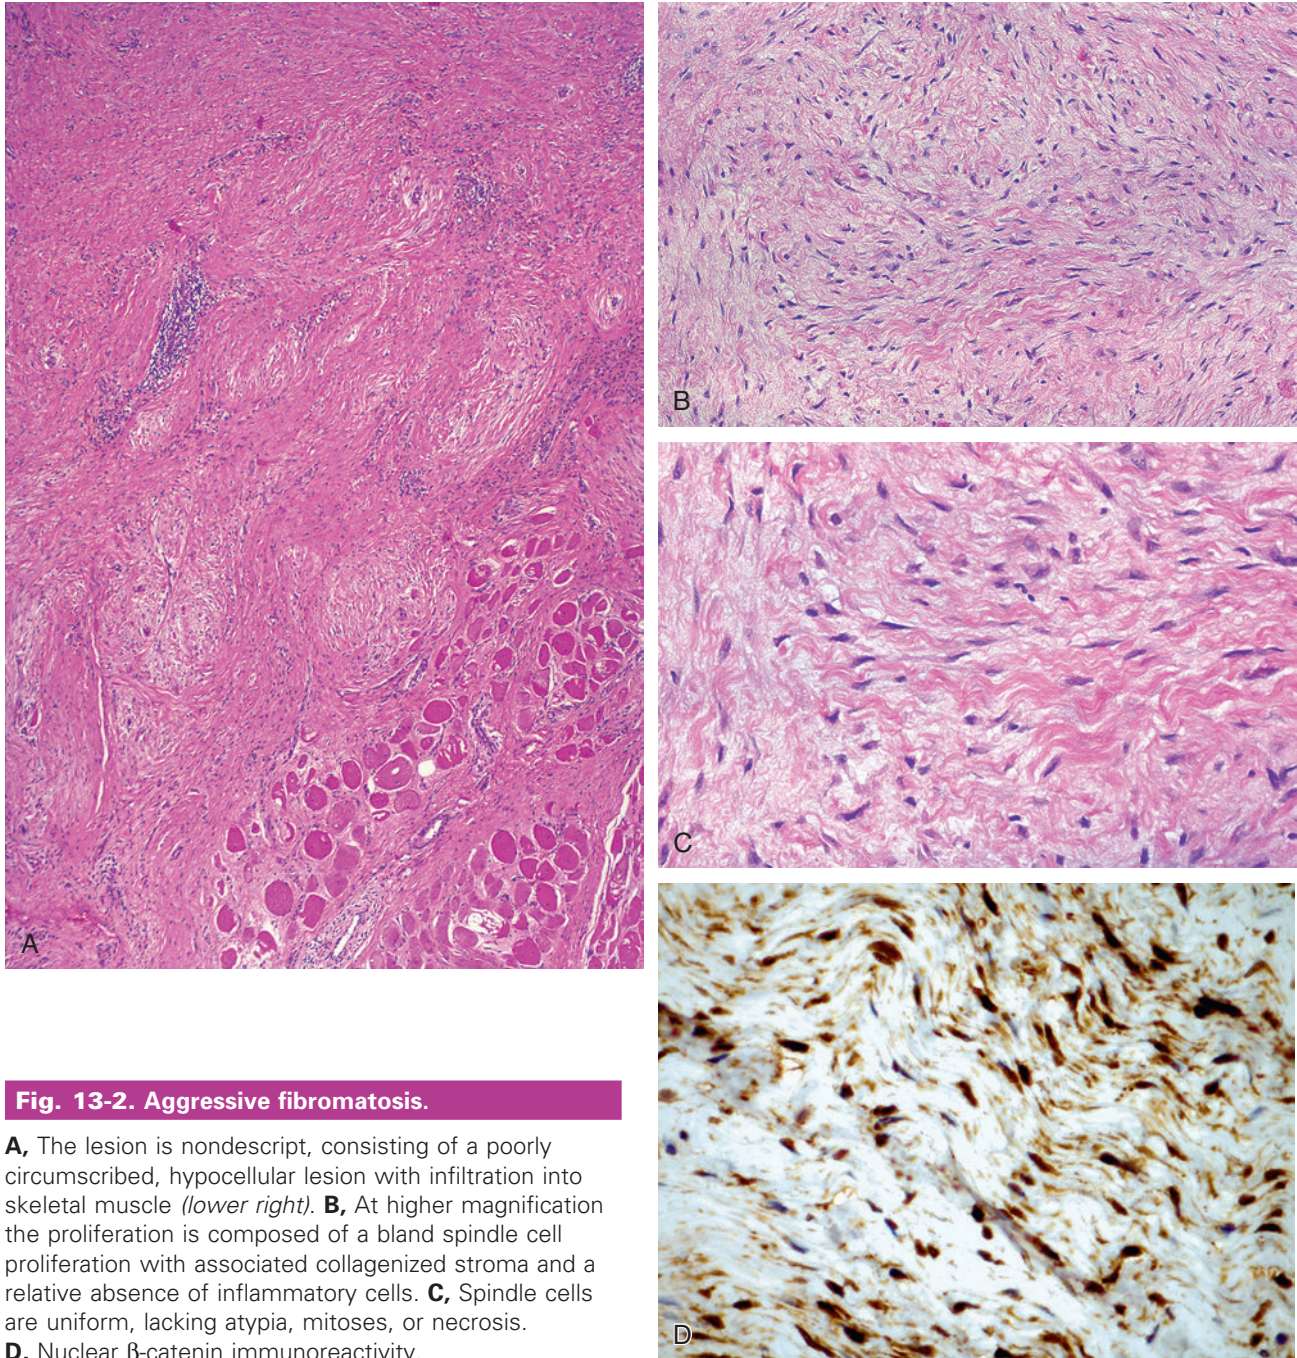

Fig. 13-2. Aggressive fibromatosis.

A, The lesion is nondescript, consisting of a poorly circumscribed, hypocellular lesion with infiltration into skeletal muscle (*lower right*). **B,** At higher magnification the proliferation is composed of a bland spindle cell proliferation with associated collagenized stroma and a relative absence of inflammatory cells. **C,** Spindle cells are uniform, lacking atypia, mitoses, or necrosis. **D,** Nuclear β -catenin immunoreactivity.

- Isodense signal intensity on T1-weighted image
- Strong MR enhancement
- Characteristic nonenhancing low signal intensity bands on all MR sequences correlate with dense collagenous stroma.
- Cause:
 - Multifactorial including genetic, endocrine, and physical factors:
 - Genetic:
 - Existence of familial cases
 - Presence of lesions in association with Gardner syndrome or Gardner-type familial adenomatous polyposis (FAP):
 - Autosomal-dominant inherited disorder characterized by the presence of intestinal polyposis, desmoid tumor, osteomas of the skull, epidermoid cysts, lipomas, and fibroma (Gardner fibroma); tumors arising in setting of FAP/Gardner syndrome harbor inactivating mutations of APC gene

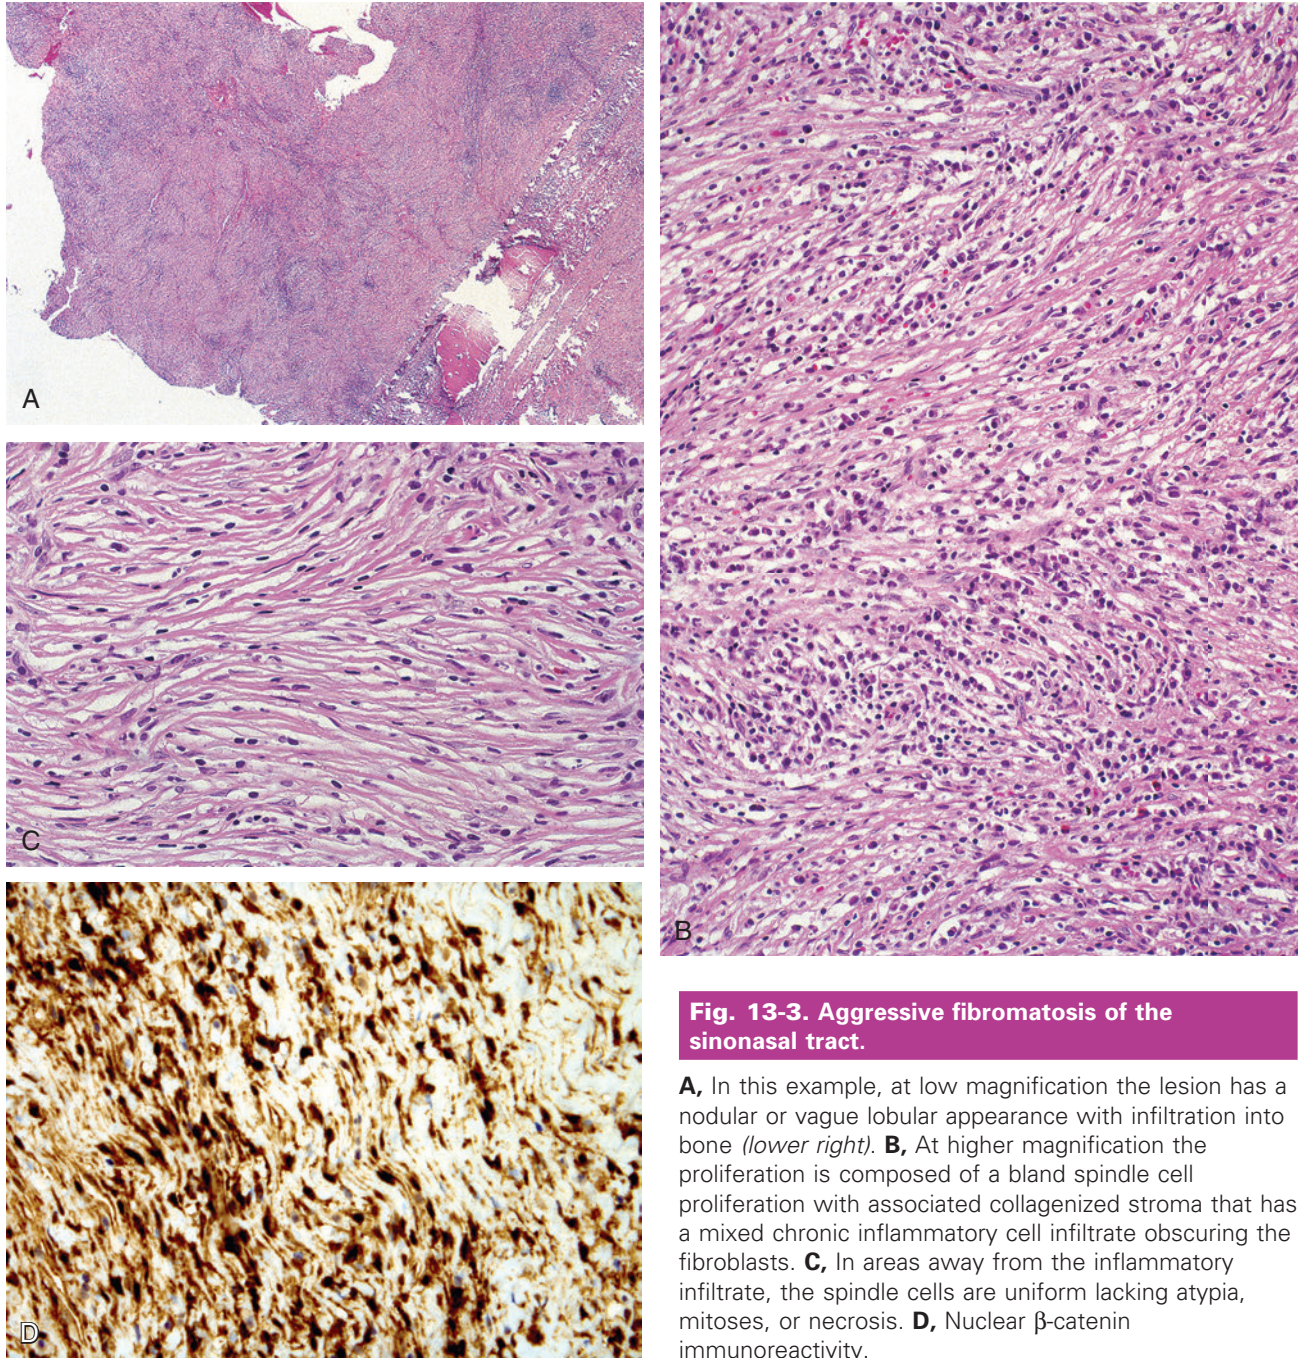

Fig. 13-3. Aggressive fibromatosis of the sinonasal tract.

A, In this example, at low magnification the lesion has a nodular or vague lobular appearance with infiltration into bone (*lower right*). **B,** At higher magnification the proliferation is composed of a bland spindle cell proliferation with associated collagenized stroma that has a mixed chronic inflammatory cell infiltrate obscuring the fibroblasts. **C,** In areas away from the inflammatory infiltrate, the spindle cells are uniform lacking atypia, mitoses, or necrosis. **D,** Nuclear β -catenin immunoreactivity.

- Gardner fibroma:
